Mechanism of Activation of Soluble Guanylyl Cyclase by NO

Allosteric Regulation through Changes in Heme Coordination Geometry

Mark F. Reynolds and Judith N. Burstyn

*Department of Chemistry
University of Wisconsin—Madison
Madison, Wisconsin*

THE NITRIC OXIDE (NO)–cGMP PATHWAY REGULATES MANY IMPORTANT PHYSIOLOGICAL PROCESSES, INCLUDING BLOOD PRESSURE, HEARING, VISION, AND NEUROTRANSMISSION, AMONG OTHERS. IN MANY CASES THE PHYSIOLOGICAL EFFECTS OF NO ARE MEDIATED THROUGH THE ENZYME RECEPTOR KNOWN AS SOLUBLE GUANYLYL CYCLASE (sGC). THIS CHAPTER PROVIDES AN OVERVIEW OF THE CHEMICAL PROPERTIES OF NO THAT MAKE IT SUCH AN UNUSUAL SENSING MOLECULE, AND IT DESCRIBES HOW NO INTERACTS WITH THE HEME COFACTOR OF NO-SENSING sGC. FIRST, A DESCRIPTION OF THE STRUCTURE AND BONDING OF METAL NITROSYLS IS PRESENTED IN ORDER TO PROVIDE A FOUNDATION FOR UNDERSTANDING THE METALLOBIOCHEMISTRY OF NO. THE REACTIVITY OF NO WITH THE IRON ATOM OF THE HEME PROSTHETIC GROUP IS THEN DESCRIBED IN SOME DETAIL, SINCE NO EXERTS ITS EFFECT BY INTERACTING WITH THE HEME IN sGC. NEXT, THE INTERACTION OF O₂ AND CO WITH OTHER GAS-SENSING HEME PROTEINS, KNOWN TO UNDERGO CONFORMATIONAL CHANGES ON BINDING THEIR MESSENGER MOLECULES, IS PRESENTED AS A PARADIGM FOR NO-SENSING sGC. AN OVERALL PICTURE OF THE MECHANISM OF NO ACTIVATION OF sGC IS DEVELOPED IN LIGHT OF THIS BACKGROUND, USING THE LATEST EXPERIMENTAL DATA ON sGC. FINALLY, INHIBITORS AND ACTIVATORS OF sGC ARE DISCUSSED, BECAUSE A PRACTICAL RESEARCH GOAL IS TO FIND SELECTIVE INHIBITORS OR ACTIVATORS OF sGC THAT MAY BE USED AS THERAPEUTIC AGENTS.

Introduction

The discovery that nitric oxide (NO) is a messenger molecule (Feldman *et al.*, 1993; Ignarro, 1999; Murad, 1999) was a surprise. Most cellular messengers are larger molecules that make specific contacts with their targets via shape

selecting, hydrogen bonding, or specific ion pairing interactions. NO, in contrast, has no obvious recognition handles other than its electron distribution and chemical reactivity. NO is able to freely diffuse through aqueous solutions or membranes, reacting rapidly with specific intracellular molecules. One set of targets for NO are the metalloproteins, and

the best-studied sensor for NO, soluble guanylyl cyclase (sGC), is a heme iron-containing metalloprotein. Metalloproteins are ideal sensors for NO because the metal centers interact both as electron acceptors and as electron donors, forming stable metal nitrosyl complexes.

Since small gaseous molecules, such as NO, exert many of their effects by interacting with the metal cofactors of metalloproteins, it is important to understand how these metal centers interact with gases. Prior to the recognition that they could serve as biological signals, NO and CO were utilized as inhibitors and probes of the active sites of metalloproteins (Antonini and Brunori, 1971). In fact, much of our understanding of how gases interact with the heme cofactor comes from studies intended to probe the function of the O₂ carrier hemoglobin (Hb) (Jameson and Ibers, 1994; Olson and Phillips, 1997). Heme proteins that sense the small molecules O₂ (Fix L) (Gilles-Gonzalez *et al.*, 1995; Tamura *et al.*, 1996; Lukat-Rodgers and Rodgers, 1997), CO (CooA) (Aono *et al.*, 1996; Shelver *et al.*, 1997), and NO (sGC) (Wolin *et al.*, 1982; Stone and Marletta, 1994; Wedel *et al.*, 1994; Yu *et al.*, 1994) have been characterized, and their function is intimately linked to the chemistry of the heme iron–gas molecule interaction. This chapter will focus on the NO-sensing enzyme sGC, the cellular receptor for NO that mediates many of the important biological effects of the NO–cGMP pathway (Ignarro, 1999). This enzyme catalyzes the conversion of guanosine-5'-triphosphate (GTP) to cyclic-3',5'-monophosphate (cGMP) and pyrophosphate (PP_i) (Fig. 1),

Figure 1 The conversion of GTP to cGMP catalyzed by soluble guanylyl cyclase (sGC). The substrate for the enzyme is MgGTP²⁻, and excess Mg²⁺ is required for maximal catalytic activity.

and, like many other gas-sensing proteins, it contains a heme prosthetic group (Fig. 2), which is the site of NO binding (Wolin *et al.*, 1982; Stone and Marletta, 1994; Yu *et al.*, 1994). NO is believed to trigger a conformational change in sGC on binding to the heme cofactor, and this structural change in turn causes a dramatic increase in the rate of enzyme turnover. Elucidating the NO-sensing mechanism of sGC has proved challenging, owing to the complexity of the enzyme and the lack of purified protein; however, an understanding of how the heme mediates the effect of NO is now emerging (Hobbs, 1997).

This chapter is structured to provide an overview of the chemical properties of NO that make it such an unusual sensing molecule, and in particular, how the properties of NO and its interactions with the heme cofactor can be used to understand the mechanism of NO-sensing by sGC. First, the structure and bonding of metal nitrosyls will be discussed in order to provide a foundation for understanding the metallobiochemistry of NO. The reactivity of NO with the heme prosthetic group will be presented in detail since it is this interaction that mediates many of the biological effects of NO. Next, the interaction of O₂ and CO with other gas-sensing heme proteins known to undergo conformational changes on binding their messenger molecules will be presented as a paradigm for NO-sensing sGC. Finally, an overall picture of the mechanism of NO activation of sGC will be developed in light of this background, using the latest experimental data on sGC. This review is intended to provide the reader with a fundamental understanding of the interactions of NO with heme proteins and, in particular, with an appreciation for how NO triggers the activation of sGC, a crucial step in the physiologically important NO–cGMP signaling pathway in mammals.

Figure 2 The structure of the heme *b* cofactor [iron(II)protoporphyrin IX] with a side on view of the axial ligands bound to the iron atom. The planar ring structure is common to all porphyrins; other heme cofactors and porphyrins have different peripheral substituents. By analogy to the hemoglobin structure, one ligand (L₂) is termed proximal, and the other (L₁) is termed distal. In subsequent figures the porphyrin is represented by a square of four N atoms, or a heavy bar on either side of the iron atom.

NO and Its Interactions with Metals: The Bonding, Structure, and Properties of Metal Nitrosyl Complexes

The transition metal ions found in metalloproteins react readily with NO to form metal nitrosyl complexes. The biologically relevant transition metals Fe, Mn, Co, Ni, V, Mo, and W all form metal nitrosyl (M–NO) complexes that have been characterized (Richter-Addo and Legzdins, 1992). The bonding in metal nitrosyl complexes has been classically described using valence bond theory by assigning formal oxidation states to the metal and the nitrosyl ligand (Moeller, 1946a,b; Griffith *et al.*, 1958; Lewis *et al.*, 1958; Raynor, 1972). The M–NO unit is either linear with the NO assigned as NO⁺ (a net donation of three electrons to the metal) or the NO is bent, with the NO assigned as NO[−] (a net donation of one electron to the metal). In valence-bond terms the NO⁺ group is considered to be *sp* hybridized, while the NO[−] unit is considered to be *sp*² hybridized. The bonding in the M–NO unit is described by a set of resonance structures, as illustrated in Fig. 3. A shortcoming of this valence-bond approach is obvious if one considers the effect of assigning oxidation states to metal nitrosyls using this bonding description. The linear metal nitrosyl complexes Mn(CO)(NO)₃ and Cr(NO)₄ would exhibit the unreasonably low metal oxidation states of −3 and −4, respectively. Furthermore, experimental and calculational evidence reveals that the M–NO linkage is strongly covalent, not ionic as implied by the valence bond formalism (Feltham and Enemark, 1981; Richter-Addo and Legzdins, 1992).

The covalent bonding in metal nitrosyls is most accurately described using molecular orbitals (Hoffman *et al.*, 1974; Feltham and Enemark, 1981). In this approach the NO ligand donates electron density to the metal through a σ type orbital and accepts electron density from the metal d orbitals through backbonding with the π^* NO orbitals (Fig. 4). This bonding scheme is analogous to the Dewar–Chatt–Duncanson description of metal carbonyl bonding (Shriver *et al.*, 1994); however, there are distinct differences between CO

Figure 3 The valence bond description of metal nitrosyls. (A) Resonance structures for a linear metal nitrosyl. (B) Resonance structures for a bent metal nitrosyl.

Figure 4 A simple molecular orbital description of metal nitrosyls. The three electrons from NO are distributed among the σ (two electrons) and π^* (one electron) symmetry orbitals of NO, and these NO orbitals interact with those of corresponding symmetry on the metal ion. (A) The σ bonding interaction between the NO σ orbital (corresponding to the lone pair on N) and the metal ion d_{z^2} orbital. (B) The π backbonding interaction between a metal orbital of π symmetry (either d_{xy} or d_{xz}) and the NO π^* orbital.

and NO as ligands for transition metals. NO is considered to be a weaker σ donor but a better π acceptor than CO (Bursten *et al.*, 1981; Bursten and Gatter, 1984). In a M–NO unit the M–N bond is typically strong and the N–O bond is weak; in contrast, in a M–CO unit the M–C bond is weak and the C–O bond is strong (Richter-Addo and Legzdins, 1992). Evidence for these differences can be seen in the differing reactivities of metal nitrosyl and metal carbonyl complexes; metal nitrosyls lose an oxygen atom to form metal nitrides whereas metal carbonyls react to displace or functionalize the CO unit (Richter-Addo and Legzdins, 1992).

A more comprehensive molecular orbital description was developed by Feltham and Enemark (1981) to explain the bonding and properties of a wide variety of metal nitrosyl complexes. The theory explains the existence of both bent and linear M–NO groups without invoking ionic character in the M–NO unit. Feltham and Enemark (1981) proposed the $\{\text{M}(\text{NO})_x\}^n$ formalism where the M–NO bonding units are considered first in generating the molecular orbital set; additional ligands can then perturb these M–NO-derived molecular orbitals. In this bonding model, the total number of electrons, n , associated with the M–NO unit includes only the d electrons from the metal and the π^* electrons from NO (one electron for each NO group). For example, $\text{Re}(\text{NO})(\text{H})_2(\text{PPh}_3)_3$ (where Ph is phenyl) is denoted $\{\text{Re}(\text{NO})\}^6$ (five d electrons from Re^{2+} and one π^* electron from NO). Feltham and Enemark (1981) were able to use this formalism to provide a basis for understanding the structures of a wide variety of metal nitrosyls. Metal nitrosyl

complexes exhibit diverse coordination modes; the NO group can bind to the metal in either a terminal mode (where the NO binds to the metal via the N atom) or a bridging mode (where the NO binds via both the N and O atoms) (Richter-Addo and Legzdins, 1992). Bridging NO ligands are typically found in multimetallic compounds. The $\{M(NO)_x\}^n$ formalism can be effectively applied to understand the bonding in all these structural types; however, we will only discuss monometallic species that contain terminal nitrosyls because it is such a complex that is formed in sGC.

The majority of terminal nitrosyl complexes that have been characterized are six-coordinate, approximately octahedral complexes, although four- and five-coordinate complexes are known (Richter-Addo and Legzdins, 1992). The bonding in these complexes is well described by the Feltham–Enemark (1981) model. In complexes of the type $\{M(NO)\}^n$, where $n = 0-6$ electrons, the valence electrons reside only in bonding and nonbonding molecular orbitals; the antibonding orbitals are empty. In such complexes the NO unit will be linear since maximum overlap can occur between the metal and NO ligand. An example is $Cr(NO)(NO_2)_2(py)_3$ (where py is pyridine) for which $n = 5$ and the M–N–O angle is 180° (Lukehart and Troup, 1977). When $n > 6$, the additional electrons would be expected to occupy a π antibonding orbital shared by M, N, and O. Instead, bending of the M–N–O unit occurs, relieving electronic strain in the complex and lowering the energy of a σ antibonding orbital with metal d_{z^2} and NO σ character (Fig. 5A) (Feltham and Enemark, 1981; Richter-Addo and Legzdins, 1992). The bond-weakening effect of adding additional electrons into an orbital that is antibonding with respect to the metal and the NO is offset by a compensatory bonding interaction between the metal d_{z^2} orbital and the NO π^* orbital (Fig. 5B). The metal–NO bond thus remains intact, although the backbonding interactions are weakened by poorer overlap (Fig. 5C and 5D). Examples of complexes with bent M–N–O units include $[Fe(NO)(das)_2(NCS)]BF_4$ [where das is *o*-phenylenebis(dimethylarsine)] for which $n = 7$ and the M–N–O angle is 140° (Enemark *et al.*, 1977), and $[Co(NO)(NH_3)_5]Cl_2$ for which $n = 8$ and the M–N–O angle is 119° (Pratt *et al.*, 1971).

Four- and five-coordinate terminal metal nitrosyl complexes have been characterized. They may be viewed as six-coordinate complexes with vacant sites, since they obey similar rules (Feltham and Enemark, 1981). Five-coordinate nitrosyl complexes can be either square pyramidal or trigonal bipyramidal, with either linear or bent M–NO units. In trigonal bipyramidal complexes, the NO group can be either axial or equatorial. As in the case of six-coordinate complexes, when the electron count in the M–NO unit is less than or equal to six, the M–NO unit is linear, and when the electron count exceeds six, the M–NO unit is bent. The majority of structurally characterized four-coordinate metal nitrosyl complexes are of the $\{M(NO)\}^{10}$ type, and they possess a pseudotetrahedral coordination geometry with linear M–NO groups (Richter-Addo and Legzdins, 1992). An exception is $(TP')CuNO$ [where TP' is tris(3-*tert*-butylpyra-

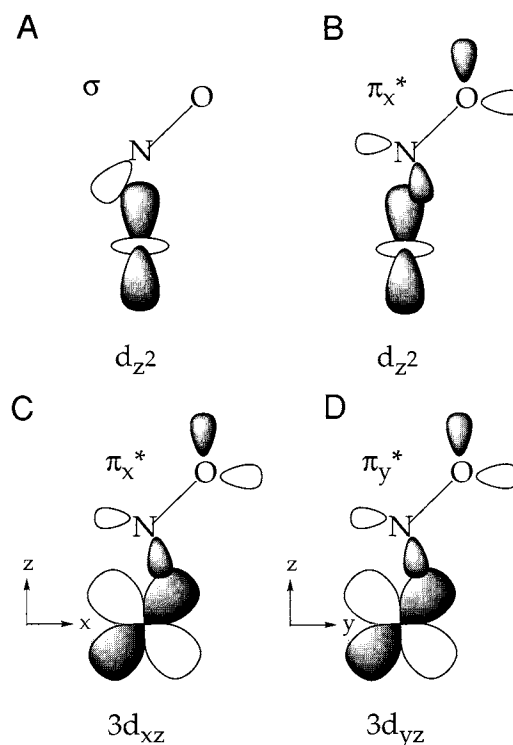

Figure 5 The orbital interactions in a bent metal nitrosyl complex. (A) Bending the NO ligand minimizes the antibonding overlap between the metal d_{z^2} orbital and the NO σ orbital. (B) A compensatory bonding interaction takes place between the NO π^* orbital and the metal d_{z^2} orbital. (C and D) Bending reduces the backbonding interactions between the metal and NO π symmetry orbitals by decreasing the orbital overlaps.

zoyl)hydroborate]; in this case, the complex is pseudotetrahedral, with $\{Cu(NO)\}^{11}$ and a Cu–N–O angle of 163° (Ruggiero *et al.*, 1993). Thus, the structure and bonding in metal nitrosyls are easily rationalized by a simplified molecular orbital approach which takes into consideration the covalency of the M–NO unit.

Because the nitrosyl formed in sGC is a nitrosyl metalloporphyrin, it is valuable to consider the structure and bonding of nitrosyl metalloporphyrins in more detail. The porphyrin ligand (Fig. 2) bears a -2 charge which is shared equally among the four pyrrole nitrogens. The nitrogens are arranged in a square plane, making the porphyrin an obligate four-coordinate ligand. There are two additional ligand binding sites above and the below the porphyrin plane where small molecules can bind to form five- and six-coordinate complexes. NO binds to metalloporphyrins to form either five-coordinate square pyramidal or six-coordinate pseudo-octahedral complexes (Richter-Addo and Legzdins, 1992). Five-coordinate nitrosyl metalloporphyrins of Groups 6 through 9, $(P)M(NO)$ where P is the dianionic porphyrin core and M a divalent metal ion, have been synthesized (Scheidt, 1977). The M–NO bond geometry is a function of the metal, as predicted by the Feltham–Enemark electron count, and is independent of the identity of the porphyrin (Fig. 6A). The Group 5 metals Cr and Mo form five-coordinate $(P)Cr(NO)$ and $(P)Mo(NO)$ complexes with a

Figure 6 Structures of five- and six-coordinate nitrosyl metalloporphyrins. (A) Five-coordinate nitrosyl metalloporphyrin complexes obey the Feltham–Enemark rules. The M–NO unit in the {Mn(NO)}⁶-type complex is linear, whereas those in {Fe(NO)}⁷- and {Co(NO)}⁸-type complexes are bent. (B) Six-coordinate Fe and Co nitrosyl metalloporphyrins exhibit an NO *trans* influence, a lengthening of the bond *trans* to NO. Six-coordinate Mn nitrosyls do not exhibit this bond lengthening. The magnitude of the bond lengthening increases from iron to cobalt, correlating with an increasing population of the antibonding d_{z^2} – σ NO orbital.

{M(NO)}⁵ electron count and linear M–N–O linkages (Diebold *et al.*, 1979; Kelly and Kadish, 1984). The Group 6 Mn ion also forms a five-coordinate (TTP)Mn(NO) complex with {M(NO)}⁶ and a linear M–NO unit (Scheidt *et al.*, 1979). In contrast, the Group 8 atoms Fe and Co form nitrosyl metalloporphyrins that have substantially bent M–N–O groups. (TPP)Fe(NO), {Fe(NO)}⁷, has a M–NO linkage of 149.2° (Scheidt and Frisse, 1975), whereas (TPP)Co(NO), {Co(NO)}⁸, has an M–N–O linkage of 135.2° (Scheidt and Hoard, 1973) or 120° in a more recent crystal structure (Richter-Addo *et al.*, 1996). The Feltham–Enemark description of the structure and bonding in metal nitrosyls thus is valid for five-coordinate nitrosyl metalloporphyrins.

Because five-coordinate nitrosyl complexes, including nitrosyl metalloporphyrins, have a vacant coordination site *trans* to the NO, they are able to bind an additional ligand. Six-coordinate Mn, Fe, and Co nitrosyl complexes have been synthesized, and they follow the structural pattern predicted by the M–NO electron count: the Mn–NO unit is linear whereas the Fe–NO and Co–NO units are bent (Richter-Addo and Legzdins, 1992). Interestingly, six-coordinate Fe nitrosyl complexes display a lengthening of the metal–

ligand bond *trans* to NO by approximately 0.2 Å (Nappier *et al.*, 1975; Scheidt and Piciulo, 1976; Enemark *et al.*, 1977; Scheidt *et al.*, 1977). This *trans* influence is clearly a consequence of the additional electron on the NO ligand, as (P)Fe(CO)(L) complexes do not exhibit this effect (Peng and Ibers, 1976; Kim and Ibers, 1991). In contrast, six-coordinate Mn nitrosyl complexes exhibit virtually no *trans* bond lengthening (Tullberg and Vannerberg, 1967; Piciulo *et al.*, 1974). Six-coordinate Co nitrosyl complexes exhibit an even greater *trans* influence than Fe nitrosyl complexes, with a *trans* bond lengthening of approximately 0.3 Å (Snyder and Weaver, 1970; Pratt *et al.*, 1971; Enemark *et al.*, 1975; Johnson *et al.*, 1976). The magnitude of the *trans* influence depends on the Feltham–Enemark electron count and the predicted occupancy of the antibonding metal d_{z^2} – σ NO orbital. As the electron count in the M–NO unit increases above six, the antibonding metal d_{z^2} – σ NO-derived orbital becomes populated, with one electron in the case of Fe–NO and two electrons in the case of Co–NO. This orbital, because of its significant metal d_{z^2} character, is also antibonding with respect to the sixth ligand; therefore, the bond to the ligand *trans* to NO is weakened when the orbital

is populated. The effect of the electron count on the *trans* influence can be clearly seen in Fig. 6B. In Fe(II)TPP(4-MePip)(NO)·CHCl₃ the Fe–N bond *trans* to NO is 0.26 Å longer than that in the analogous Mn complex, and 0.33 Å longer than other Fe–N bonds (Piciulo *et al.*, 1974; Scheidt *et al.*, 1977). Co(II)TPP will not bind a sixth ligand at all, existing as five-coordinate Co(II)TPP(NO) even in pure 4-methylpiperidine (Scheidt and Hoard, 1973). As we will discover shortly, the structure and bonding of these nitrosyl metalloporphyrins provides a foundation for understanding the coordination changes that occur when NO binds to the heme of sGC.

The Interaction of NO with the Heme Cofactor of Heme Proteins

Heme-containing proteins are a diverse family found in almost all forms of life. There is a vast literature on heme proteins; some good general reviews are available for those readers who require more information than is provided in this chapter (Durham and Millet, 1994; English, 1994; Goff, 1994; Jameson and Ibers, 1994; Lippard and Berg, 1994; Walker and Simonis, 1994). All heme proteins contain a heme prosthetic group with a single iron atom bound in a square planar array by the four pyrrole nitrogens of the porphyrin (Fig. 2). The oxidation state of the iron is typically either +2 (ferrous) or +3 (ferric), although more highly oxidized states are attainable in certain cases. When the iron is bound in the dianionic porphyrin core, the net charge on a ferrous heme is 0 and on a ferric heme is +1. The protein typically provides one or two additional ligands to the iron atom which bind in the axial positions above and below the porphyrin plane, forming a five- or six-coordinate iron complex. These positions are designated proximal and distal on the basis of their relationship to hemoglobin structure; in hemoglobin the proximal histidine is the heme ligand, and the distal histidine stabilizes the bound oxygen with a hydrogen bond. The heme iron is bound through coordinate covalent bonds to amino acids bearing Lewis basic donor sites. Common heme ligands include histidine, providing an imidazole donor, cysteine, a thiolate donor, tyrosine, a phenolate donor, and methionine, a thioether donor. Less common ligands are the amine on a lysine side chain or the N terminus of the protein. The substituents attached to the porphyrin macrocycle determine the type of heme cofactor. Heme *b*, also known as protoheme or iron protoporphyrin IX, is the cofactor found in hemoglobin and sGC. There are other types of heme cofactors that occur naturally in biology; these include hemes *a* and *d* that contain a polyisoprene tail connected to the porphyrin and hemes *c*, *c'*, and *f* that form covalent thioether bridges to two cysteine thiolate residues of the protein. Hemes *a*, *b*, and *d* are noncovalently bound to the protein by ionic and hydrophobic interactions between the heme cofactor and the protein matrix.

The electronic state of the heme is modulated by the protein environment and plays an important role in the function

of a heme protein (Jameson and Ibers, 1994; Walker and Simonis, 1994). The oxidation state of the heme depends on the conditions and the redox potential of the specific heme protein. The presence of two strong field axial ligands yields a low-spin heme, whereas the presence of a single axial ligand typically yields a high-spin heme. Common strong field ligands include histidine, cysteine (thiolate), tyrosine (phenolate), methionine, OH[−], CN[−], N₃[−], CO, and NO. Weak field ligands include water, F[−], thiols, and alcohols. The possible spin states for the *d* electrons in ferric heme proteins are either high spin ($S = \frac{5}{2}$), intermediate spin ($S = \frac{3}{2}$), or low spin ($S = \frac{1}{2}$), depending on the heme environment. The spin states of ferrous heme are either low spin ($S = 0$) or high spin ($S = 2$); the $S = 1$ intermediate-spin state is not observed in biological ferrous heme proteins (Jameson and Ibers, 1994; Walker and Simonis, 1994). The most important point to emphasize concerning the electronic structures of heme proteins is that the energy differences between spin states are typically small, and the protein environment can exert an enormous influence on the spin state, and thus the function, of the heme cofactor in a protein.

Heme proteins that have only one axial amino acid ligand typically bind to a variety of exogenous ligands, and these ligand interactions have been used to characterize the heme environment. The most widely studied heme proteins are hemoglobin and myoglobin; both contain a high-spin heme bound by a histidine imidazole (Jameson and Ibers, 1994; Lippard and Berg, 1994). Oxygen binds directly to the ferrous heme, forming a six-coordinate complex that retains the histidine ligand. Other neutral ligands such as imidazole and CO can also bind to the heme of ferrous (deoxy) hemoglobin (Antonini and Brunori, 1971; Jameson and Ibers, 1994). Neutral ligands typically bind more tightly to the electron-rich ferrous heme than to ferric heme. In contrast, negatively charged exogenous ligands such as CN[−], N₃[−], or F[−] bind preferentially to the more highly charged ferric heme. Addition of a sixth axial ligand to either a ferrous or a ferric heme that is five-coordinate and high spin results in conversion to a six-coordinate, low-spin heme (Antonini and Brunori, 1971; Jameson and Ibers, 1994). The changes in heme coordination environment on binding exogenous ligands can be monitored by a variety of spectroscopic methods, providing a wealth of information on the heme environment, including in many cases the identity of the protein-derived axial ligand.

Nitric oxide reacts readily with the iron of heme proteins, binding even more strongly to ferrous heme than O₂ or CO (Antonini and Brunori, 1971; Traylor and Sharma, 1992; Olson and Phillips, 1997a). The greater affinity of NO for heme, when compared to the affinity of CO for heme, can be attributed to differing dissociation rates; the dissociation rate constant for loss of NO from deoxyhemoglobin is much smaller, 10^{−5} s^{−1}, than that for loss of CO, 20 s^{−1}, whereas the association rates for the two gases are comparable (Doyle and Hoekstra, 1981; Olson *et al.*, 1997). Another important difference between NO and CO is that while CO only binds to Fe(II) hemes, NO binds to both Fe(II) and Fe(III) hemes

(Antonini and Brunori, 1971). On binding to some ferric heme proteins, including hemoglobin, the NO reduces the heme to the ferrous state, and a second NO molecule binds to form the stable Fe(II)–NO adduct (Antonini and Brunori, 1971; Addison and Stephanos, 1986). The effect of NO on the binding of a sixth ligand is readily seen in thermodynamic studies of ligand binding in iron carbonyl and iron nitrosyl heme complexes (Fig. 7) (Traylor and Sharma, 1992). NO thermodynamically favors formation of a five-coordinate NO–heme complex. CO, in contrast, prefers to form a six-coordinate CO–heme, with an axial ligand bound. Also, NO binds to heme in a bent fashion, whereas CO binds to heme in a linear fashion. These observations are easily rationalized in terms of the electron counts of the NO and CO complexes. The Fe(II)–CO unit, with electron count {Fe–CO}⁶ (the CO donates 0 π^* electrons), forms a linear M–CO unit; a base readily binds to the sixth coordination position. In contrast, the Fe(II)–NO unit, with electron count {Fe–NO}⁷, forms a bent M–NO unit, and the binding of the sixth ligand is destabilized by the population of the antibonding d_{z^2} – σ NO orbital. The relative instability of the six-coordinate ferrous nitrosyl heme is an important contributor to the mechanism of NO activation of sGC.

The cooperative binding of oxygen to hemoglobin is the paradigm for allosteric regulation of protein function and serves as a foundation for our understanding of sGC. Structural and spectroscopic studies since the 1940s have elucidated the specific changes that occur when O₂ binds to the heme iron (Goff, 1994; Jameson and Ibers, 1994; Lippard and Berg, 1994); it is the interaction of the oxygen molecule with the heme that triggers the allosteric change from the

Figure 7 Thermodynamics of CO and NO binding to heme in the presence and absence of an additional axial ligand. (A) The binding affinity of CO for heme is highest in the presence of a sixth ligand. The presence of CO enhances the affinity of the iron porphyrin for the sixth ligand. (B) The binding affinity of NO for heme is highest in the absence of a sixth ligand. The presence of NO decreases the affinity of the iron porphyrin for the sixth ligand. Adapted with permission from Traylor and Sharma (1992). Copyright 1992 American Chemical Society.

Figure 8 Allosteric control in hemoglobin. The binding of O₂ to a heme triggers a conformational change in the protein that allows hemoglobin to cooperatively bind additional O₂ molecules. Low-spin iron is smaller than high-spin iron and makes shorter bonds to its ligands; in order to maintain ideal bonding distances to the four porphyrin nitrogens, the proximal histidine and the O₂, the iron moves into the porphyrin plane, pulling on the proximal histidine and the F helix.

low-affinity T state to the high-affinity R state (Fig. 8). Hemoglobin is an $\alpha_2\beta_2$ tetramer that contains one heme b group per subunit. In the deoxy ferrous state, the hemes are bound by an imidazole nitrogen from the proximal histidine. The high-spin iron atom is displaced somewhat toward the histidine ligand, and when oxygen binds to a ferrous heme, it converts the heme to low spin and pulls the iron atom into the plane of the heme. This motion is triggered by the smaller ionic radius of the low-spin oxy heme. The movement of the heme iron pulls the proximal histidine toward the heme, and the histidine in turn pulls the F helix of the protein. The displacement of the iron-proximal histidine unit by approximately 0.6 Å leads to a 6-Å movement of the hemoglobin subunits due to changes in salt bridges and hydrogen bonding contacts. This conformational change is what enables hemoglobin to cooperatively bind oxygen. The paradigm provided by hemoglobin, which will be invoked to understand sGC, is that it is a change in the heme coordination environment that triggers the allosteric conformational change.

Other Gas-Sensing Heme Proteins

It has been recognized that there are other heme proteins that serve as gas sensors in prokaryotic organisms, employing allosteric mechanisms similar to that of hemoglobin. The FixL proteins are heme-containing, O₂-sensing protein kinases from plant rhizobial symbionts. FixL phosphorylates transcription factors that control the expression of genes for nitrogen fixation (Gilles-Gonzalez *et al.*, 1995; Tamura *et al.*, 1996; Lukat-Rodgers and Rodgers, 1997). A FixL protein can be divided into three functional domains, a membrane-binding domain, a heme-binding domain, and a kinase domain. Much has been learned about the function of

the FixL protein through the study of the isolated heme domain. The heme cofactor is a high-spin ferrous heme with a single histidine (H194) bound to the iron (Nakamura *et al.*, 1998). Oxygen binding to the heme causes a spin state transition from high-spin to low-spin heme, as occurs in hemoglobin, and this spin state change triggers a conformational change that regulates the activity of the kinase domain (Fig. 9) (Gong *et al.*, 1998). FixL is active as a kinase in the high-spin state and inactive in the low-spin state, regardless of the oxidation state of the heme. Strong field ligands, including O_2 , trigger the transition to low-spin heme and inactivate the protein (Gilles-Gonzalez *et al.*, 1994; Gong *et al.*, 1998). FixL thus senses O_2 via a conformational change mediated by the interaction of O_2 with its heme prosthetic group, a mechanism analogous to the cooperative binding of O_2 by hemoglobin.

The first CO-sensing protein, CooA, was purified from the photosynthetic bacterium *Rhodospirillum rubrum* (Aono *et al.*, 1996; Shelver *et al.*, 1997) and provides another important example of a gas-sensing heme protein. CooA is a transcription regulator and a member of the CRP (cAMP receptor protein) and FNR (fumarate nitrate reduction) family of transcription regulators. In the presence of CO, CooA binds to DNA and turns on the expression of a multicomponent CO-oxidation system in *R. rubrum* (Shelver *et al.*, 1995; He *et al.*, 1996). This CO-oxidation system catalyzes the anaerobic conversion of CO to CO_2 and allows growth with CO as the sole energy source (Shelver *et al.*, 1995; He *et al.*, 1996). Unlike FixL and hemoglobin, the heme in CooA is low spin, apparently bearing two protein-derived ligands in both the ferric and ferrous state (Aono *et al.*, 1998; Shelver *et al.*, 1999). In ferric CooA one axial ligand is cysteine (Aono *et al.*, 1998; Reynolds *et al.*, 1998; Shelver *et al.*, 1999); on reduction the cysteine–thiolate is replaced by a histidine (Aono *et al.*, 1998; Shelver *et al.*, 1999; Vogel *et al.*, 1999a). CO induces DNA binding via a conformational change in CooA by displacing one of the ligands from the ferrous heme (Aono *et al.*, 1998; Reynolds *et al.*, 1998; Shelver *et al.*, 1999; Vogel *et al.*, 1999a); available evidence suggests that it is the histidine that is displaced (Fig. 10) (Vogel *et al.*, 1999a). Like hemoglobin and FixL, CooA is

proposed to undergo a conformational change that is triggered by the binding of a small molecule, in this case CO, to the heme cofactor.

Soluble Guanylyl Cyclase: A Heme-Dependent NO Sensor

The guanylyl cyclases (GCs) are a diverse family of enzymes that convert guanosine-5'-triphosphate (GTP) to cyclic-3',5'-monophosphate (cGMP) and pyrophosphate (PP_i). There are two genetically distinct subtypes of guanylyl cyclase, the particulate (membrane bound) form (pGC) and the soluble form (sGC) (Garbers *et al.*, 1994; Garbers and Lowe, 1994b). The soluble isoform was discovered in mammalian cells in the late 1960s (Hardman and Sutherland, 1969; Schultz *et al.*, 1969; White and Aurbach, 1969) and has been found in a wide variety of organisms including mammals (Feldman *et al.*, 1993; Hobbs, 1997), the fruitfly *Drosophila melanogaster* (Liu *et al.*, 1995; Shah and Hyde, 1995), the roundworm *Caenorhabditis elegans* (Yu *et al.*, 1997), and the yeast *Saccharomyces cerevisiae* (Kuo *et al.*, 1998). Only the soluble enzyme contains heme and functions as an NO sensor; the activity of sGC is increased several hundredfold on binding NO (Hobbs, 1997).

There is at present a limited amount of information regarding the structure of sGC. The enzyme is an $\alpha\beta$ heterodimer composed of two closely related subunits (Koesling *et al.*, 1988, 1990). Enzyme activity is observed only when both subunits are present, implying that only the heterodimer is catalytically active (Wedel *et al.*, 1995). It is not known, however, whether the isolated α and β subunits homodimerize. There appear to be three functional domains in each sGC subunit; an N-terminal heme-binding domain, a C-terminal catalytic domain, and a dimerization domain (Fig. 11). The role of the putative dimerization domain is little studied; the assignment of this region is based simply on homology to pGC. The C termini of the sGC subunits bear strong homology to the C_1 and C_2 catalytic domains of adenylyl cyclase (AC) (Koesling *et al.*, 1988, 1990; Liu *et al.*, 1997). The sGC catalytic domain has been modeled onto the AC catalytic domain structure; the successful fit implies that the sGC active site is formed at the interface of the α and β subunits (Liu *et al.*, 1997). The heme binding domain has been the subject of a number of studies that will be discussed later.

Knowledge of the catalytic mechanism of sGC derives from enzymological studies and structural analogy to the related AC enzymes. The stereochemistry of cyclization for both sGC and AC is known; in both enzymes the reaction proceeds with inversion of configuration at the α phosphate (Gerlt *et al.*, 1980; Eckstein *et al.*, 1981; Senter *et al.*, 1983; Koch *et al.*, 1990). These data are consistent with direct nucleophilic attack of the ribose 3'-hydroxyl on the 5'- α -phosphate of GTP or ATP (Fig. 1). A reasonable mechanism, proposed for AC on the basis of structural analysis, invokes the presence of a catalytic base on the enzyme that would

Figure 9 The mechanism of O_2 sensing by FixL. The binding of O_2 to the heme iron of FixL converts the heme from high spin to low spin, triggering a conformational change in the protein. O_2 binding to the heme inactivates the kinase activity of FixL.

Figure 10 The proposed mechanism for CO sensing by CoxA. Oxidized, Fe(III)CooA contains a low-spin heme with two ligands bound to the heme iron. One ligand is a cysteine (Cys⁷⁵) that is proposed to be hydrogen bonded to a nearby histidine, His⁷⁷. The identity of the other ligand, labeled X, is unknown. On reduction to Fe(II)CooA, Cys⁷⁵ is displaced by His⁷⁷ to form an imidazolate-bound heme that is presumably stabilized by hydrogen bonding to the nearby Cys⁷⁵. CO displaces a ligand, most likely the His⁷⁷–Cys⁷⁵ ligand diad from the heme iron, triggering a conformational change in the protein. When CO is bound, CoxA can bind to its target DNA sequence. accept the proton from the ribose 3'-hydroxyl, rendering it a more effective nucleophile (Tesmer *et al.*, 1997; Zhang *et al.*, 1997). The leading candidate for this catalytic base is an aspartate residue that is near the ribose 3'-hydroxyl in the crystal structure of AC. An analogous residue appears in all GC isoforms in homology models and has been shown to be essential for catalysis in several AC and GC isoforms (Yuen *et al.*, 1994; Tang *et al.*, 1995; Thompson and Garbers, 1995; Liu *et al.*, 1997).

Essential divalent metal ion cofactors are necessary for cyclase activity and may be involved in binding the negatively charged substrate, stabilizing the transition state, and polarizing the 3'-hydroxyl nucleophile. The AC crystal structure reveals one Mg²⁺ in position to stabilize both the assumed pentavalent transition state and the pyrophosphate leaving group (Tesmer *et al.*, 1997). It is also proposed that a second metal ion, not present in the crystal structures, participates in polarizing the 3'-hydroxyl of ATP (Mitterauer *et al.*, 1998; Zimmerman *et al.*, 1998). Both AC and GC enzymes are known to require Mg²⁺ in excess of the MgGTP²⁻ substrate for maximal activity, implicating additional metal ions in the catalytic mechanism; the absence of a second metal ion in the crystal structures may be a consequence of the fact that the crystals were grown in the absence of substrate or substrate analogs. In addition to metal cations, arginine and asparagine residues in the vicinity of the active site are essential for activity, perhaps by stabilizing the negatively charged transition state and leaving group via hydrogen bonding (Liu *et al.*, 1997; Tesmer *et al.*, 1997). A plausible mechanism for AC is shown in Fig. 12.

Nothing is known about the conformational change that occurs at the active site of cyclase enzymes in response to regulators. All known cyclases, including all AC and GC

isoenzymes, are regulated by isoform-specific modulators (Sunahara *et al.*, 1996; Hobbs, 1997; Wedel and Garbers, 1997). Although the specific ligands that activate or inhibit the different enzymes are distinct, there are similarities in the enzyme response. AC and GC enzymes have low activity in the absence of ligands but are typically activated substantially on binding activator ligands (Sunahara *et al.*, 1996; Hobbs, 1997; Wedel and Garbers, 1997). Although the natural divalent cation cofactor is doubtless Mg²⁺, Mn²⁺ can support catalytic activity (Sunahara *et al.*, 1996; Hobbs, 1997; Wedel and Garbers, 1997). Interestingly, the enzymes are more active in the presence of Mn²⁺ than Mg²⁺, but are less responsive to activating ligands. It has therefore been suggested that the configuration of the second metal ion binding site is altered in the activated state. Clearly, an important challenge in cyclase enzymology is the elucidation of the structural change that results in heightened catalytic activity.

Early insights into the mechanism by which NO activated sGC were obtained through studies of activation by heme analogs. A number of compounds, including PPIX (protoporphyrin IX, with no metal ion present) and NO-heme [Fe(II)PPIX(NO)] (Ohlstein *et al.*, 1982), activated sGC by a heme-independent mechanism; only enzyme deficient in heme was activated by PPIX and NO-heme. Importantly, PPIX and NO-heme activated heme-deficient sGC in a manner kinetically identical to activation of heme-containing sGC by NO (Wolin *et al.*, 1982). All the activators increased the V_{\max} by approximately 40-fold and decreased the K_m for MgGTP²⁻ by approximately one-half (Wolin *et al.*, 1982). These data suggest that there is a single activated conformation formed when the enzyme is activated by different effectors. Other porphyrins and metalloporphyrins

Figure 11 Proposed domain structure for sGC. The enzyme is heterodimeric, composed of three functional domains: a heme domain that binds NO, a cyclase catalytic domain that converts GTP to cGMP, and a dimerization domain that presumably allows the heme and cyclase domains to communicate through a conformational change. The active site within the catalytic domain is formed at the interface of the two subunits.

Figure 12 The proposed reaction mechanism for adenylyl cyclase. Aspartate-354 is proposed to serve as the catalytic base, whereas Asn-1007 is thought to play a role in stabilizing the oxyanion nucleophile. The essential Arg-1011 is positioned to stabilize the negative charge of the pentavalent transition state. At least one Mg^{2+} cation also plays a role in catalysis and is believed to stabilize the departing pyrophosphate. Figure adapted with permission from Liu *et al.* (1997). modulated sGC activity, and the nature of the effect varied with the identity of the metal ion in the porphyrin and with the substitution pattern on the porphyrin periphery (Ignarro *et al.*, 1984a). The metalloporphyrins Fe(II)PPIX, Mn(II)PPIX, and Zn(II)PPIX all inhibited sGC activity (Ignarro *et al.*, 1984a). These metalloporphyrins were competitive with respect to activation by NO-heme (in heme-deficient sGC) and NO (in heme-containing sGC), suggesting that the metalloporphyrins were interacting at the heme binding site (Ignarro *et al.*, 1984b). Similarly, when the vinyl substituents of PPIX were substituted with polar groups or the propionic acids esterified, the porphyrins became competitive inhibitors of activation by PPIX (Ignarro *et al.*, 1984a). Together these results point to the importance of both the metal ion and the porphyrin periphery in accessing the activated conformation of sGC.

Other compounds, including NO, nitroso compounds, and phenylhydrazine, activate sGC in a heme-dependent manner (Craven and DeRubertis, 1978; Ignarro *et al.*, 1984c). Heme-containing enzyme was activated 10-fold by phenylhydrazine in the presence of catalase (Craven and DeRubertis, 1978) and over 100-fold by NO (Ignarro *et al.*, 1984c). NO activation of sGC was potentiated under reducing conditions, in the presence of dithiothreitol, ascorbate, cysteine, or glutathione. In contrast, phenylhydrazine-mediated activation required another heme protein, catalase, and O_2 (Ignarro *et al.*, 1984c). Certain heme proteins, including catalase, are known to form phenyl-heme when exposed to phenylhydrazine in the presence of oxygen; presumably it was the phenyl heme that activated sGC. This observation pointed to a remarkable feature of sGC: the ability of sGC to extract heme from other heme proteins. Indeed, it was subsequently demonstrated that heme-deficient sGC could be fully activated by NO-catalase or NO-myoglobin and that in the activation process, the NO-heme was transferred to sGC (Ignarro *et al.*, 1986).

What conclusions can be drawn from these early studies of sGC activation? The activation of sGC by NO is heme dependent, suggesting that the heme is the site of NO interaction with the protein. NO binds to Fe(II) heme in myoglobin and hemoglobin to form a stable Fe(II)–NO complex

under anaerobic conditions (Antonini and Brunori, 1971); therefore, it is logical to conclude that NO is binding to the heme of sGC. The observation that preformed NO-heme activates heme-deficient sGC strongly supports this conclusion. The activation of sGC by the porphyrin PPIX suggests that the central metal is not essential; however, the sensitivity of the enzyme to the porphyrin peripheral substitution suggests that the porphyrin periphery plays an important role. The kinetic similarity between protoporphyrin IX-, NO-, and NO-heme-mediated activation suggests that there is a single conformation for the activated enzyme. These observations are all consistent with a model for NO activation of sGC, shown schematically in Fig. 13, in which NO binds directly to the heme of sGC, forming a five-coordinate NO–heme complex in which the axial ligand is displaced from the heme. The loss of the axial histidine ligand, in the presence of specific protein contacts with the heme periphery, modulates the conformational change to the activated state. This model is strongly supported by data from more recent spectroscopic studies, as will be described in detail later in this chapter.

Because sGC activity is regulated by the interaction of NO with the heme cofactor, there has been great interest in learning about the heme environment in the enzyme. A number of mutagenesis studies have been performed to identify the region of the protein where heme is bound and to identify the liganding amino acids. Wedel *et al.* (1994) mutated seven conserved histidines in the α and β subunits outside the catalytic domains. Interestingly, one variant protein, sGC β -H105F (with the histidine at position 105 of the β subunit changed to phenylalanine), exhibited basal catalytic activity but was unresponsive to NO and did not contain detectable heme. This result provided circumstantial evidence that β -H105 was a ligand to the heme. More recently, Zhao and Marletta (1997) cloned and expressed the N-terminal domain of the β subunit, β 1–385, in *Escherichia coli*. This truncated protein contained a stoichiometric amount of heme and exhibited spectral properties similar to those of the intact enzyme (Zhao and Marletta, 1997; Schelvis *et al.*, 1998; Zhao *et al.*, 1998a). When the histidine at position 105 was replaced by glycine, the variant protein did not bind heme;

Figure 13 Proposed mechanism of activation of sGC by NO. The binding of NO to the heme of sGC displaces the heme ligand. The change in heme coordination is believed to trigger a structural change in the cyclase catalytic site that dramatically increases the production of cGMP. Figure adapted with permission from Dierks *et al.* (1997). Copyright 1997 American Chemical Society.

however, restoration of heme binding was achieved by the addition of imidazole to the buffer medium (Zhao *et al.*, 1998b). The spectroscopic properties of the restored heme–imidazole complex were identical to those of the wild-type β 1–385 fragment. These data provided convincing evidence that β -H105 is indeed the heme ligand. Although the β subunit N terminus appears sufficient for heme binding, it is possible that both the α and β subunit N termini are necessary for configuring the heme binding site in the full-length enzyme. When the N terminus of either the α (131 residues) or the β (64 residues) subunits were removed, alteration of catalytic function and NO sensitivity were observed, supporting the theory that the heme is cooperatively bound by both subunits (Foerster *et al.*, 1996). Because the β 1–385 fragment was isolated as a homodimer (Zhao *et al.*, 1998b), the possibility remains that the heme binding site is configured by the homodimeric structure.

Characterization of the heme environment of sGC has revealed inconsistency in behavior. The enzyme has been isolated from bovine lung and spectroscopically characterized in two distinct forms, differing in their heme content and spectroscopic properties. Unlike most other heme proteins that bind heme tightly, the heme in sGC can be lost during purification (Gerzer *et al.*, 1981a). An explanation for this loss has been proposed: oxidation of the heme to the ferric state renders the heme more labile, thus oxidation during purification would result in a heme-deficient protein (Dierks and Burstyn, 1998). The first form of sGC, called sGC₁ in this chapter, contains substoichiometric levels of heme after purification. This form of sGC has been characterized from two sources: direct isolation of the bovine lung enzyme (Yu *et al.*, 1994; Burstyn *et al.*, 1995) and overexpression of the enzyme in insect cells (Fan *et al.*, 1998). The sGC₁ protein can be reconstituted with ferrous heme to yield heme loaded enzyme that is activated by NO (Yu *et al.*, 1994; Burstyn *et al.*, 1995; Fan *et al.*, 1998). The second form, called here sGC₂, has also been isolated from bovine lung and expressed in insect cells; sGC₂ is isolated with stoichiometric amounts of ferrous heme (Stone and Marletta, 1994; Tomita *et al.*, 1997; Makino *et al.*, 1999). Although it was first suggested that sGC₂ contained two hemes per heterodimer (Stone and Marletta, 1995a), more recent analysis suggests that there is only one mole of heme per sGC heterodimer (Brandish *et al.*, 1998). The two forms of the protein exhibit different properties: heme-reconstituted sGC₁ in the ferrous state is readily oxidized in air and subsequently loses heme (Burstyn *et al.*, 1995), whereas sGC₂ in the ferrous state is completely unreactive toward oxygen, and the heme remains stably bound to the protein. The complete lack of reactivity toward oxygen is unusual; most ferrous heme proteins either bind to or are oxidized by oxygen (Antonini and Brunori, 1971). Oxidation of sGC₂ can be achieved with ferricyanide (Stone *et al.*, 1996), and the resulting ferric protein does not lose heme. Both sGC₁ and sGC₂ exhibit similar specific activity and sensitivity to activation by NO (Stone and Marletta, 1995a; Vogel *et al.*, 1999b). It is unclear why sGC isolated from the same source has distinctly different

properties; plausible explanations include isolation of different isoforms, or failure of the heme reconstitution process to regenerate the native heme binding conformation. As will be described next, the two forms of the protein have different spectroscopic properties.

Recent spectroscopic studies of sGC have provided the first glimpse into the coordination environment of the heme iron in the presence and absence of NO. Enzyme isolated with less than stoichiometric amounts of heme, sGC₁, was reconstituted under reducing conditions with ferrous heme for spectroscopic study; the reconstituted samples were substantially activated by NO, suggesting that the reconstituted ferrous heme was bound in a functionally correct manner (Burstyn *et al.*, 1995; Dierks *et al.*, 1997). The electronic absorption spectrum of heme-reconstituted sGC₁ exhibited a Soret band at 426 nm and α , β bands at 558 and 528 nm, respectively (Burstyn *et al.*, 1995; Vogel *et al.*, 1999b). This spectrum is typical for ferrous heme bound by two histidines, such as is the case in cytochrome *b₅*. Additional spectroscopic studies sensitive to the heme environment, including resonance Raman (Yu *et al.*, 1994; Fan *et al.*, 1998; Vogel *et al.*, 1999b) and magnetic circular dichroism studies (Burstyn *et al.*, 1995), revealed a mixture of five- and six-coordinate heme, with the six-coordinate form predominant. The spectral features were consistent with the presence of two histidines bound to the heme iron. One of these ligands was observed to be photolabile, an uncommon feature observed in other heme proteins and attributed to strain (Yu *et al.*, 1994). The second type of sGC isolated from bovine lung, sGC₂, contains one heme per sGC heterodimer, and it is isolated with the heme in the reduced ferrous state. The electronic absorption spectrum of ferrous sGC₂ exhibits a Soret band at 431 nm and a single α/β band at 555 nm (Stone and Marletta, 1994; Tomita *et al.*, 1997; Makino *et al.*, 1999); this spectrum is similar to those of deoxyhemoglobin and myoglobin, proteins known to contain high-spin, histidine-coordinated ferrous heme. Resonance Raman spectra of sGC₂ are also consistent with a high-spin, five-coordinate heme, and direct observation of the Fe–His stretching mode provides conclusive evidence for histidine as the axial ligand (Denium *et al.*, 1996; Tomita *et al.*, 1997). The low frequency of the Fe–His stretch is consistent with a weak or strained Fe–His bond. The ferrous forms of sGC₁ and sGC₂ differ in coordination number at the heme (Fig. 14); sGC₁ contains largely six-coordinate, bishistidine-ligated heme, whereas sGC₂ contains high-spin, five-coordinate heme with a single histidine ligand. At least one of the ligands is weak or under strain in both forms.

The ferric states of sGC₁ and sGC₂ also exhibit different properties, consistent with differing coordination numbers in the two proteins. Heme-reconstituted sGC₁ was observed to rapidly lose heme on oxidation with ferricyanide or O₂, with a half-life of 60 min (Dierks and Burstyn, 1998). The electronic absorption spectrum of ferric sGC₁ exhibited a Soret band at 420 nm and α/β bands at 541 and 572 nm, consistent with the presence of a low-spin, six-coordinate ferric heme (Burstyn *et al.*, 1995). Cyanide (CN[−]) did not significantly

Figure 14 Coordination states of the two types of sGC that have been spectroscopically characterized. (A) sGC₁ is predominantly six-coordinate in the Fe(II) and Fe(III) oxidation states, with two histidine ligands bound to the heme iron. (B) sGC₂ is five-coordinate in both oxidation states with a single histidine bound. Both sGC₁ and sGC₂ react with NO to form a five-coordinate nitrosyl heme, with displacement of the protein derived ligand(s).

alter the electronic or magnetic circular dichroism (MCD) spectra even at 250 mM, supporting the conclusion that the ferric state is six-coordinate (Burstyn *et al.*, 1995). In contrast, the ferric state of sGC₂ generated by ferricyanide oxidation did not lose heme and the oxidation/reduction process was reversible (Stone *et al.*, 1996). The electronic spectrum of ferric sGC₂ exhibited a Soret band at 393 nm consistent with a high-spin, five-coordinate heme (Stone and Marletta, 1994). The electron paramagnetic resonance (EPR) spectrum confirmed the presence of a high-spin ferric heme (Stone *et al.*, 1996). Consistent with a five-coordinate geometry, ferric sGC₂ bound typical ferric heme ligands such as cyanide, azide, and fluoride to form six-coordinate adducts (Stone *et al.*, 1996). Thus, the coordination number observed in each enzyme form is consistent between the two redox states, and in most cases the ligand-binding behavior correlates as expected, with only the five-coordinate sGC₂ reacting to form six-coordinate adducts. A surprising exception is the reaction with dioxygen; it is the five-coordinate sGC₂ that is unreactive, whereas six-coordinate sGC₁ is readily autoxidized.

Direct interaction of NO with the heme of sGC has been confirmed through spectroscopic studies. The Fe(II)–NO adduct of sGC, Fe(II)sGC(NO), has been characterized by electronic absorption (Stone and Marletta, 1994; Vogel *et al.*, 1999b), EPR (Stone *et al.*, 1995), and resonance Raman spectroscopy (Yu *et al.*, 1994; Denium *et al.*, 1996; Tomita *et al.*, 1997; Fan *et al.*, 1998; Vogel *et al.*, 1999b). The electronic absorption spectrum of NO bound to both ferrous sGC₁ (Gerzer *et al.*, 1981a; Ignarro *et al.*, 1986; Burstyn *et al.*, 1995; Vogel *et al.*, 1999b) and sGC₂ (Stone and Marletta, 1994; Tomita *et al.*, 1997; Makino *et al.*, 1999) exhibits a shallow, blue-shifted Soret band at ~399 nm characteristic of a five-coordinate nitrosyl heme species (Antonini and Brunori, 1971; Scholler *et al.*, 1979). Resonance Raman spectra of NO bound to either sGC₁ (Fan *et al.*, 1998; Vogel *et al.*, 1999b) or sGC₂ (Denium *et al.*, 1996; Tomita *et al.*, 1997) are similarly indicative of a five-coordinate nitrosyl heme (Choi *et al.*, 1991; Lukat-Rodgers and Rodgers, 1997; Vogel *et al.*, 1999c). The EPR spectrum of Fe(II)sGC(NO) exhibits the three-line rhombic signal characteristic of five-coordinate nitrosyl heme proteins and model compounds (Kon, 1968; Yonetani *et al.*, 1972; Hille *et al.*, 1979; Yoshimura, 1982; Tsai, 1994; Stone *et al.*, 1995; Makino *et al.*, 1999). In both forms of sGC, sGC₁ and sGC₂, the protein-derived ligand(s) are displaced by NO, forming a five-coordinate nitrosyl heme (Fig. 14). The two enzyme forms differ, however, in the apparent polarity of the pocket surrounding the NO ligand (Denium *et al.*, 1996; Vogel *et al.*, 1999b). It is the displacement of the axial histidine ligand or ligands by NO that is believed to trigger the conformational change, resulting in greatly increased enzyme turnover.

The importance of ligand displacement in NO activation of sGC has been demonstrated using nonnative metalloporphyrin substitution. To test the hypothesis that loss of the axial ligand was a key requirement for activation, the ability of NO to displace the axial ligand was systematically altered by varying the electron count at the metal center. Reconstitution of fully heme-depleted sGC₁ with Mn(II)PPIX and Co(II)PPIX produced new proteins, Mn(II)sGC and Co(II)sGC, with novel metal centers (Dierks *et al.*, 1997). These nonnative metalloporphyrins were predicted to form NO complexes with electron counts of {Mn–NO}⁶ and {Co–NO}⁸, respectively, and loss of the ligand *trans* to NO was predicted to occur with Co but not with Mn. Characterization of Mn(II)sGC and Co(II)sGC by electronic absorption and resonance Raman spectroscopy revealed that both nonnative metalloporphyrins were five-coordinate with a single histidine ligand (Fig. 15A) (Dierks *et al.*, 1997). A more recent study of Co(II)sGC confirmed the presence of a single nitrogen ligand through the observation of superhyperfine coupling between one ¹⁴N and the Co nucleus in the EPR spectrum (Makino *et al.*, 1999). When NO was added, Mn(II)sGC(NO) appeared to retain the histidine ligand, forming a six-coordinate nitrosyl adduct (Fig. 15A), as evidenced by peak positions in the electronic spectrum. In contrast, Co(II)sGC(NO) formed a five-coordinate nitrosyl adduct (Fig. 15B), in which the axial histidine was dis-

Figure 15 Coordination states of nonnative metalloporphyrins substituted for the heme in sGC. (A) Mn(II)sGC is five-coordinate with a single histidine ligand. Mn(II)sGC reacts with NO to form a six-coordinate nitrosyl, Mn(II)sGC(NO). Mn(II)sGC(NO) exhibits only basal activity. (B) Co(II)sGC is five coordinate with a single histidine ligand. Co(II)sGC reacts with NO to form five-coordinate Co(II)sGC(NO) with displacement of the histidine ligand. Co(II)sGC(NO) is more active than native Fe(II)sGC(NO). Figure adapted with permission from Dierks *et al.* (1997). Copyright 1997, American Chemical Society.

placed as determined from the similarity of the resonance Raman spectrum of Co(II)sGC(NO) to those of model five-coordinate nitrosyl cobalt porphyrin complexes (Dierks *et al.*, 1997; Makino *et al.*, 1999). Thus, the two nonnative metal-substituted enzymes attained the coordination geometry predicted by the Feltham–Enemark electron count when NO was bound. Importantly, the coordination at the metal center correlated with the activity of the enzyme: NO did not activate Mn(II)PIX-reconstituted sGC, but it did activate Co(II)PIX-reconstituted sGC (Dierks *et al.*, 1997). The magnitude of activation correlated with the magnitude of metal–ligand bond weakening predicted by the electron count as Co(II)sGC(NO) exhibited consistently greater activity than Fe(II)sGC(NO).

There is direct evidence that an axial histidine ligand is displaced when NO binds to sGC. Experiments on native, heme-containing sGC₂ reveal that a six-coordinate nitrosyl heme is formed initially when NO binds to sGC (Makino *et*

al., 1999). This six-coordinate nitrosyl heme exhibited an EPR spectrum consistent with the presence of an axial histidine ligand *trans* to the NO. Furthermore, this species decayed directly to the five-coordinate nitrosyl heme observed previously. Thus, activation of sGC by NO can be directly linked to displacement of the axial ligand from the heme iron. From all these studies, it can be concluded that nature utilizes the coordination preferences and specificity of NO binding to heme to regulate the conformational change of sGC. NO binding triggers the release of the histidine ligand by weakening the bond between iron and histidine.

Other Regulators of sGC

Molecules other than NO may also regulate sGC activity through interaction with the heme. It has been proposed that CO, another well-known heme ligand, may serve as a physiological regulator of sGC, and biological evidence implicates the enzyme heme oxygenase as a source of CO in a variety of tissues (Maines, 1988). Production of CO leads to elevation of cGMP, and increased cGMP correlates with physiological responses, including vascular relaxation and neurological function (Maines, 1988; Verma *et al.*, 1993). These data imply that sGC activity *in vivo* is responsive to CO. Unfortunately, direct activation of sGC by CO has not been observed *in vitro*; isolated sGC enzyme is activated only minimally (two- to sixfold) by CO (Brune and Ullrich, 1987; Stone and Marletta, 1994; Burstyn *et al.*, 1995; Friebe *et al.*, 1996; Makino *et al.*, 1999; Vogel *et al.*, 1999b). Although CO does not directly activate sGC, it has been discovered that the effect of CO is dramatically enhanced by the xenobiotic 3-(5'-hydroxymethyl-2'-furyl)-1-benzylindazole (YC-1) (Friebe *et al.*, 1996; Stone and Marletta, 1998). In the presence of YC-1 and CO, sGC activity is comparable to that with NO alone. It is therefore possible that an endogenous compound exists that potentiates activation of sGC by CO.

Consideration of binding affinities suggests that CO is unlikely to compete effectively with NO for the heme of sGC at physiological concentrations of these gases. Available data suggest that NO binds to sGC many orders of magnitude more strongly than does CO. The dissociation rate of CO from the heme of sGC is exceptionally fast ($3.5\text{--}28\text{ s}^{-1}$), whereas the association rate is comparable to that of Hb and Mb ($3.6 \times 10^4\text{--}1.2 \times 10^5\text{ M}^{-1}\text{ s}^{-1}$) (Stone and Marletta, 1995b; Kharitonov *et al.*, 1997). The enzyme therefore has a weaker affinity for CO ($K \approx 10^3\text{ to }10^4\text{ M}^{-1}$) than Mb and Hb. Comparable data for NO binding to sGC reveal an NO association rate of $7.8 \times 10^8\text{ M}^{-1}\text{ s}^{-1}$ and a dissociation rate of $\sim 0.01\text{ to }1\text{ s}^{-1}$ (Stone and Marletta, 1996; Kharitonov *et al.*, 1997). Thus, the affinity of NO for sGC is approximately 10^{10} . These data reveal a six order of magnitude preference of the sGC heme for NO over CO, suggesting that under physiological conditions NO will bind to sGC regardless of the CO concentration (Vogel *et al.*, 1999b). It is possible, however, that CO interacts with the heme of sGC in tis-

sues where NO is not present, or under as yet undetermined conditions where the preference of the enzyme is less pronounced.

The CO adduct of sGC has been characterized, and, in contrast to NO, it forms a six-coordinate carbonyl heme in both sGC₁ and sGC₂ (Fig. 16). The electronic spectra of the CO adducts of both sGC₁ (Gerzer *et al.*, 1981b; Burstyn *et al.*, 1995; Vogel *et al.*, 1999b) and sGC₂ (Stone and Marletta, 1994; Tomita *et al.*, 1997) are similar, with a Soret maximum at ~420 nm and well-defined α/β bands, consistent with a low-spin, six-coordinate carbonyl heme in both forms of the enzyme. The electronic spectra are very similar to those of the carbonyl adducts of hemoglobin and myoglobin, where the ligand *trans* to CO is known to be histidine (Antonini and Brunori, 1971). The MCD spectrum of Fe(II)sGC₁(CO) is similar to that of other six-coordinate histidine-bound heme proteins such as the CO adducts of hemoglobin and horseradish peroxidase (Burstyn *et al.*, 1995). The resonance Raman spectra of the CO adducts of sGC₁ (Yu *et al.*, 1994; Fan *et al.*, 1998; Vogel *et al.*, 1999b) and sGC₂ (Kim *et al.*, 1996; Tomita *et al.*, 1997) reveal similarities and some striking

differences. Both Fe(II)sGC₁(CO) and Fe(II)sGC₂(CO) exhibit spectra consistent with a six-coordinate histidine-bound heme. The CO ligand appears to be in a hydrophobic environment in the case of sGC₁, but in a negatively polarized environment in the case of sGC₂. The origin of these polarity differences is not known, but the data clearly implicate different heme binding environments in the two forms of sGC. The failure of either enzyme form to become activated in the presence of CO correlates with the presence of an intact iron–histidine bond in the CO adducts, further supporting the idea that loss of the axial ligand is required for activation.

There are few selective activators or inhibitors of sGC known, making sGC an undeveloped drug target for regulation of the NO–cGMP pathway. Viagra, a drug that has received much recent attention, inhibits the breakdown of cGMP by the cGMP-dependent phosphodiesterase, acting one step downstream from sGC in the NO–cGMP pathway. It is believed that sGC plays an important role in the NO–cGMP pathway and that defects in sGC regulation, resulting in either overactivity or underactivity, may be involved in certain pathologies (Hobbs, 1997; Ignarro, 1999; Murad, 1999). For example, septic shock and migraines result from overactivity of the NO–cGMP pathway, whereas impotence, hypertension, and asthma result from underactivity (Hobbs, 1997). Furthermore, when produced inappropriately, NO can interfere with or destroy critical cellular systems. An important goal in sGC research is to develop sufficient understanding of the protein to enable the development of selectively targeted drugs.

Of the few inhibitors known, a number are redox active compounds that may interact with the heme of sGC. Methylene blue and LY83583 are the most widely used inhibitors of sGC (Fig. 17), but their action is not selective for sGC inhibition (Hobbs, 1997; Dierks and Burstyn, 1998). A plausible explanation for the inhibition of sGC by these redox dyes includes reaction with heme or NO. A new inhibitor, ODQ (1*H*-[1,2,4]oxadiazolo[4,3-*a*]quinoxalin-1-one) (Fig. 17), was shown to be a potent inhibitor of NO-induced smooth muscle relaxation (Brunner *et al.*, 1995; Garthwaite *et al.*, 1995). Studies with purified sGC revealed that ODQ maintains the heme in the oxidized state even in the presence of NO (Schrammel *et al.*, 1996). Although the most specific inhibitor known, ODQ may have limited application *in vivo* given that it interacts with the heme groups of other proteins (Feelisch *et al.*, 1999). The compound YC-1 (Fig. 17) has provided a selective, non-NO-based activator of sGC that is functional *in vivo* (Ko *et al.*, 1994). Although the mechanism of YC-1 activation is not clear, YC-1 may help to stabilize the activated state of sGC by binding to an allosteric site on the protein (Friebe *et al.*, 1996; Stone and Marletta, 1998).

Figure 16 Coordination states of the CO adduct of sGC. CO binds to the hemes of both Fe(II)sGC₁ and Fe(II)sGC₂ to form six-coordinate carbonyl adducts in which the iron–proximal histidine bond remains intact. CO does not significantly activate either sGC₁ or sGC₂.

Conclusions

Future work on sGC will doubtless improve our understanding of the structural basis for NO activation of sGC.

Figure 17 Known inhibitors and activators of sGC. Methylene blue and LY83583 are the most widely used inhibitors of sGC, but their action is not selective. ODQ (1H-[1,2,4]oxadiazolo[4,3-a]quinoxalin-1-one) is a more selective inhibitor of sGC, but its usefulness *in vivo* may be limited due to interaction with other heme proteins. The compound YC-1 [3-(5'-hydroxymethyl-2'-furyl)-1-benzylindazole] is a selective activator of sGC that is functional *in vivo*.

Although the heme of sGC has been conclusively identified as the receptor for NO, and changes in heme coordination geometry on binding NO are clearly important in the activation process, many key questions remain. What structural changes occur in the enzyme upon NO binding to the heme of sGC? What changes in the catalytic site are responsible for the dramatic increase in cyclase activity? How do the heme and the cyclase sites communicate? How is sGC deactivated, since the off rate for NO from hemes is too slow for simple NO dissociation to be relevant? It is hoped that future studies will answer these questions and lead to the development of specific inhibitors and activators of sGC as new therapeutic tools. It is certain that extensive research on sGC in the next few years will vanquish its title as the "forgotten sibling" of the cyclases.

Cyclic GMP-Mediated Signaling Mechanisms in Smooth Muscle

Thomas M. Lincoln and Padmini Komalavilas

*The Department of Pathology, Division of Molecular and Cellular Pathology,
University of Alabama at Birmingham, Birmingham, Alabama*

IT IS WIDELY APPRECIATED THAT NITRIC OXIDE (NO) IS AN IMPORTANT CELLULAR REGULATOR THAT EXERTS MAJOR EFFECTS ON PROCESSES AS DIVERSE AS THE REGULATION OF VASCULAR TONE AND SYNAPTIC TRANSMISSION AND PLASTICITY. ALTHOUGH NO—COMPOSED OF ONLY TWO ATOMS—IS ONE OF THE SIMPLER CHEMICAL STRUCTURES IN BIOLOGY, ITS EFFECTS ON CELLS ARE UNUSUALLY COMPLEX. THIS CHAPTER EXAMINES THE MOST WIDELY UTILIZED NO SIGNAL TRANSDUCTION PATHWAY, THE CYCLIC GMP/cGMP-DEPENDENT PROTEIN KINASE (PKG) SYSTEM, IN THE REGULATION OF SMOOTH MUSCLE TONE. PARTICULAR EMPHASIS IS PLACED ON THE ROLE OF PKG IN SMOOTH MUSCLE SINCE IT IS NOW APPARENT THAT THIS KINASE IS A CRITICAL CONTROL POINT FOR INTRACELLULAR CALCIUM REGULATION, CONTRACTILE PROTEIN FUNCTION, AND GENE EXPRESSION.

Introduction

The major components of the cGMP signaling pathway in eukaryotic cells were first described in the 1970s. Today, cGMP signaling is one of the more widely studied cellular pathways, owing in part to the importance of nitric oxide (NO) in cellular function. The important contribution of NO to the discipline of cGMP signaling is illustrated in Fig. 1. In Fig. 1A and 1B, the number of publications dealing with cGMP was relatively modest but actually outpaced those dealing with NO until 1992. Publications dealing with either cGMP or cGMP-dependent protein kinase (PKG, Fig. 1C), in fact, had remained somewhat constant or only slightly increased between 1988 and 1992. Since 1992, however, papers dealing with NO have increased logarithmically. As a result of such broad interest in NO, publications dealing with cGMP and particularly PKG have likewise dramatically increased. Thus, prior to the widespread interest in the role of NO in biological systems, a smaller group of investigators held exclusive province in the cGMP/PKG field. The

broader interest in cGMP/PKG signaling pathways seen today had to await the emergence of the more translationally applicable NO paradigm.

The ancient history involving cGMP signaling before NO appeared on the scene may seem irrelevant. However, many of the current controversies surrounding the roles of NO, cGMP, and the PKG in cell function might be partially resolved when examined in light of some of the older findings regarding cGMP signaling. This chapter will cover many basic aspects of NO–cGMP signaling, but with emphasis on the role of cGMP and PKG in smooth muscle function. Special consideration will be given to the pitfalls regarding interpretation of the published information from current studies. Limitations on space will by necessity mean that some topics concerning this signal transduction system will not be covered. Nor will all the relevant citations for the work described below be included. Nevertheless, it is hoped that the topics covered will provide a potent stimulus for research on this signaling pathway.

Figure 1 Yearly publications on NO, cGMP, and PKG.

NO-Cyclic GMP Signaling via Protein Phosphorylation

Cyclic GMP is a major mediator of NO signaling in the cell by virtue of the high affinity of NO for the soluble form of guanylate cyclase (sGC). Estimates for the affinity of NO for the sGC-bound heme range from 50 pM to 1 nM (Hobbs, 1997). Binding of NO to sGC increases the V_{max} of the enzyme by more than 200-fold, depending on assay conditions (Hobbs, 1997). Such robust amplification is the hallmark of second messenger signal transduction as originally proposed for hormones that activate adenylate cyclase. The fate of cGMP in the cell is likewise similar to that of cAMP: first, cGMP may be hydrolyzed by cyclic nucleotide phosphodiesterases, some of which are specific for cGMP (Juilfs *et al.*, 1999). Second, cGMP may bind to one of three classes of intracellular receptor proteins (Lincoln and Cornwell, 1993): (i) cyclic nucleotide-dependent protein kinases, which include cAMP-dependent protein kinase (PKA) as well as PKG; (ii) ion channels, primarily nonspecific cation channels whose activity is increased on cGMP binding; and (iii) cyclic nucleotide phosphodiesterases, primarily at allosteric sites located on the enzymes. For the purposes of this review, we will concentrate on the cyclic nucleotide dependent kinases as mediators of NO-cGMP signal transduction.

Cyclic GMP-Dependent Protein Kinase

PROPERTIES

PKG is a modular gene product whose evolution represents the fusion of unrelated coding regions giving rise ul-

Figure 2 Structure of PKG from vertebrate sources. The domain structure for PKG is illustrated for type I (I) and type II (II) PKG. The positions of the conserved lysine and phosphorylated threonine residues are identified in the catalytic domain. The positions of conserved threonine (serine in type II PKG) in the cGMP binding sites are also shown. The domains for dimerization, autoinhibition, autophosphorylation, and cooperativity are demonstrated also.

mately to a highly regulated enzyme (for reviews, see Lincoln and Cornwell, 1993, Hofmann *et al.*, 1992, Francis and Corbin, 1994, and Butt *et al.*, 1993). As illustrated in Fig. 2, the enzyme is a serine/threonine kinase consisting of a C-terminal catalytic domain that is homologous with other kinases including tyrosine kinases. A critical lysine, an ATP binding pocket, and an activating phosphorylation site are all present in its structure. The regulatory domain is fused to the catalytic domain via a short hinge sequence and consists of an N-terminal leucine/isoleucine zipper motif, an autophosphorylation/autoinhibitory region, and two homologous cyclic nucleotide binding domains. As illustrated in Table I, there are two genes that encode PKG in mammals: the type I gene and type II gene. The Type I gene gives rise to alternatively spliced mRNAs to produce a type I α PKG and a type I β PKG (Francis *et al.*, 1988–1989; Orstavik *et al.*, 1997). In mammals, isoforms of Type II PKG have yet to be described, and they may not exist.

PKG is activated by either low concentrations of cGMP or higher concentrations of cAMP. The concentrations of cyclic nucleotides needed to activate PKG, however, depend on the isoform and the phosphorylation state of the enzyme. All PKG isoforms exist as homodimers; cyclic nucleotides bind to two nonidentical binding sites on each protomer such that four molecules of cyclic nucleotide are bound per active dimer (Francis and Corbin, 1994; Corbin *et al.*, 1986). Substitution of hydrogen with a bulky group at the 8-position of the purine ring (e.g., 8-bromo, 8-chlorophenylthio) renders a cyclic nucleotide more potent in activating the type I isoform of PKG (Francis and Corbin, 1994; Francis *et al.*, 1988). Hence, 8-chlorophenylthio-cAMP is almost as potent an activator of the I α isoform of PKG than is native cGMP itself. Experiments in which 8-substituted cyclic nucleotides are added to cells or tissues over a period of minutes to hours have resulted in the activation of both cyclic nucleotide kinases, a phenomenon known as “cross-activation” (Francis *et al.*, 1988). Thus, one pitfall with the interpretation of experiments using 8-substituted cyclic nucleotides, especially

Table I Mammalian Cyclic GMP-Dependent Protein Kinases

^aPKG I α , I β , and II have all been shown to exist as homodimers.

where the I α isoform is involved, is activation of both cyclic nucleotide-dependent protein kinases. It is advisable to construct dose-response curves using cyclic nucleotide analogs to determine the efficacy, and hence the specific kinase, involved in the biological effect under consideration.

Activation of PKG has been studied most thoroughly for the Type I isoform, and is a complex process involving the binding of cyclic nucleotides to both sites with subsequent induction of phosphorylation of serine and threonine residues in the autoinhibitory region (Hofmann *et al.*, 1985; Landgraf *et al.*, 1986; Smith *et al.*, 1992). The “slow” binding site (referred to as such due to the slow dissociation rate for cGMP) has a high affinity for cGMP ($K_{act} \cong 0.1 \mu M$ depending on the isoform), whereas the “fast” site has a lower affinity for cGMP. Because basal cGMP levels are generally less than micromolar in cells, it is likely that only the slow site is occupied during resting cellular conditions. This may contribute to the partial activation of the enzyme which is seen both in the intact cell as well as in purified enzyme preparations (Smith *et al.*, 1986). The fast site is then thought to be a “trigger” site that induces maximal activation of the enzyme. Although the binding sites for cyclic nucleotides are identical for PKG I α and I β , the I α isoform is activated by lower cGMP ($K_{act} = 0.1 \mu M$) than the I β isoform ($K_{act} = 1.0 \mu M$), suggesting perhaps that the autoinhibitory domain of I β is more efficient in maintaining basal activity of the enzyme (Francis and Corbin, 1994). The greater susceptibility of the I α isoform to cyclic nucleotide-dependent activation may account for some of the differences observed when PKG is transfected into cultured cells in order to observe specific biological effects.

Cyclic AMP binds primarily to the slow site of PKG-I, and affinity is increased more than 30-fold by autophosphorylation of the enzyme (Dorskland *et al.*, 1986). Thus, at physiological levels of cAMP (i.e., $0.5 \mu M$), cAMP would be expected to bind to autophosphorylated PKG-I. It has been known since the mid 1970s that the binding of cAMP to PKG is of relatively high affinity because immobilized cAMP columns are routinely used in the purification of PKG. Because the levels of cAMP are some 10- to 20-fold higher than cGMP in most cell types, it is likely that cAMP can trigger PKG activation in the absence of increases in cGMP. Such cross-activation of PKG by physiological in-

creases in cAMP levels has been demonstrated in coronary arterial smooth muscle strips (Jiang *et al.*, 1992).

The molecular basis for selectivity of cyclic nucleotide binding to PKG has been studied by Shabb *et al.* (1990, 1991). On alignment of the cyclic nucleotide binding sites of the regulatory subunits of PKA with the binding sites in the regulatory domains of PKG, a critical role for the hydroxyl group in threonine, found only in PKG isozymes to hydrogen bond with the C-2 amino group of the guanine ring, was described (Fig. 3). Because alanine is substituted for threonine in the regulatory subunit of PKA, no high-affinity hydrogen bonding is available for cGMP. Mutation of the alanine residues in the regulatory subunit of PKA to threonine residues resulted in high affinity binding of cGMP to PKA, providing strong support for the notion that the selectivity for cyclic nucleotide binding to cyclic nucleotide-dependent protein kinases is explained in part by a one amino acid substitution.

The expression pattern of PKG illustrates that this enzyme is far from a “housekeeping” gene product. Type I α is expressed in all smooth muscles, and it is the principal isoform expressed in platelets, cerebellum, and lung—most probably airway and pulmonary vascular smooth muscle cells (VSMC) (Lincoln and Cornwell, 1993; Butt *et al.*, 1993; Lincoln, 1994; Lincoln and Corbin, 1983). PKG-I β has been reported to be expressed at higher levels in nonvascular smooth muscle such as uterine and intestinal smooth muscle cells (Keilbach *et al.*, 1992). Type II PKG expression appears to be restricted to intestinal epithelial cells, chondrocytes, and certain regions of the brain (Jarchau *et al.*, 1994; Markert *et al.*, 1995; Uhler, 1993; Pfeifer *et al.*, 1996). And finally, it has been known for decades that many cell types appear to be practically devoid of any isoform of PKG (skeletal muscle myocytes, erythrocytes, possibly hepatocytes, and many cultured cells). Investigators need to be aware of the variable pattern of PKG expression when designing experiments to test the role of this enzyme in cell function. This is especially important given the fact that specific inhibitors and activators of the PKG pathway do not exist (see “Protein Kinase Inhibitors”).

The variability of PKG levels in tissues suggests that physiological regulation of PKG expression exists. One example of the regulation of PKG expression is found in

Figure 3 Structure of the cAMP binding site in PKA (top panel) and cGMP binding site in PKG (bottom panel). The model was predicted from the three-dimensional structure of the binding pocket of the cAMP-activator protein (CAP) of *Escherichia coli*. Cyclic GMP-selective binding pockets have threonyl residues located in the positions occupied by alanine in cAMP binding proteins. [From Shabb *et al.* (1990), reprinted with permission from the American Society for Biochemistry and Molecular Biology.]

VSMC. Primary cultures of aortic smooth muscle cells from rodent, for instance, have high levels of PKG- α . On passaging, the levels of PKG drop precipitously such that after three or four passages, expression is nearly undetectable (Cornwell and Lincoln, 1989; Cornwell *et al.*, 1994a; Wyatt *et al.*, 1998). On the other hand, high-density culture conditions and cell–cell contact induce PKG expression in VSMC, whereas low-density growth and reduced cell–cell

contact causes a loss of expression (Cornwell *et al.*, 1994a). High cell density-dependent expression of PKG may explain why passaging reduces PKG since, by definition, cell–cell contact is disrupted. There may be cell adhesion molecule signaling pathways that regulate PKG expression in VSMC, but these have not been defined.

Another mechanism for the regulation of PKG expression has been uncovered involving NO itself (Soff *et al.*, 1997). As shown in Fig. 4, chronic exposure to high concentrations of NO-donor drugs, *S*-nitroso-*N*-acetylpenicillamine (SNAP) or sodium nitroprusside (SNP), suppresses PKG mRNA in primary cultures of VSMC. The effects of NO-donor drugs on PKG expression were mimicked by exposure of the cells to cyclic nucleotide analogs. It was suggested that chronic NO-induced suppression of PKG may underlie, in part at least, the phenomenon of nitrate tolerance (Soff *et al.*, 1997). Alternatively, chronic NO production such as that which occurs as a result of NO synthase II (iNOS) induction during inflammation may suppress PKG expression in arterial smooth muscle. Reduced PKG expression may be one mechanism leading to the modulation of VSMC from a contractile phenotype to a more synthetic one in response to vascular injury (Boerth *et al.*, 1997) (see “Cyclic GMP and VSMC Phenotypic Modulation”).

PKG SUBSTRATES

An active area of research concerns substrate proteins for the PKG. In the 1970s, it was noted that PKG and PKA catalyzed the phosphorylation of the same proteins *in vitro* (Lincoln and Corbin, 1977). The substrate specificity for both kinases was defined by a cluster of basic amino acid residues N-terminal to the phosphorylated residue (Lincoln and Corbin, 1977). PKG recognizes both the sequence RKXS as well as RRXS in substrate proteins. Studies by Dostemann and co-workers (Tegge *et al.*, 1995) using combinatorial peptide libraries as substrates for cyclic nucleotide-dependent protein kinases suggest that the arginine–lysine (i.e., RK) combination may be preferred by PKG over the arginine–arginine (RR) combination. PKA, on the other hand, has a strong preference for the arginine–arginine com-

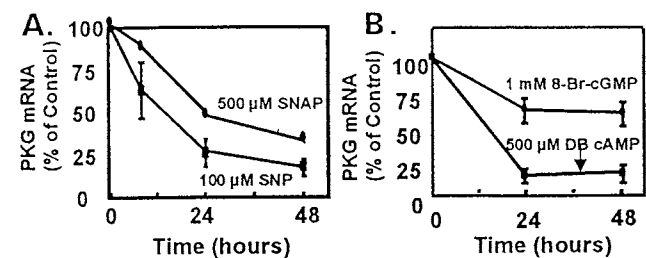

Figure 4 Effects of NO-donor drugs and cyclic nucleotide analogs on PKG expression in cultured bovine aortic smooth muscle cells. (A) Cells were treated with either SNAP or SNP. (B) Cells were treated with either 1 mM 8-Br-cGMP or 500 μ M dibutyl-cAMP. PKG mRNA was determined by Northern blot analysis. [From Lincoln *et al.* (1998). *Acta Physiol. Scand.* 164, 507–515. bination. Another determinant for PKG, at least in some protein substrates, is a preference for an aromatic residue (i.e., F or Y) four positions C-terminal to the phosphorylatable residue (Colbran *et al.*, 1992a). Despite these findings, no universal paradigm distinguishing PKA and PKG substrate specificity has emerged, suggesting that perhaps primary sequence alone is not the only determinant of substrate specificity for PKG. From the standpoint of experimental protocols, however, it is critical that investigators understand the overlapping nature of substrate specificity between these two enzymes *in vitro*, and to be knowledgeable of the fact that nonphysiological phosphorylation of proteins in the intact cell is likely to occur in response to overexpression of cyclic nucleotide-dependent protein kinases. Such a phenomenon may underlie some of the reported effects of PKG on MAP kinase activity and gene expression (see section on cyclic GMP and cell growth).

Some of the more exciting advances in our understanding of the physiological role of PKG have resulted from the identification of substrate proteins in the intact cell. Table II provides a list of some substrates for PKG likely to be physiologically important. In most these cases, specificity for PKG-dependent phosphorylation has been demonstrated and stoichiometry of phosphorylation has been obtained. Other proteins reported to be phosphorylated by PKG, but not listed in Table II, may be omitted because the studies (i) lacked controls for ruling out preference for PKA-dependent phosphorylation, (ii) demonstrated nonstoichiometric phos-

phorylation, or (iii) were based mainly on the use of inhibitors. There are molecular processes or events that are known to be regulated by PKG, but in several instances, specific substrate proteins underlying these processes have yet to be identified. Some of these events are provided in Table III and will be discussed in more detail in subsequent sections of this chapter.

Cyclic AMP-Dependent Protein Kinase

As mentioned above, cGMP also activates PKA. Unlike the case for endogenous cAMP activating PKG in the intact cell, it is probably a rare event when cGMP levels reach high enough concentrations to cross-activate PKA. In two pathological instances, however, this has been demonstrated. In human colonic carcinoma T84 cells, bacterial heat-stable enterotoxin (STa) elevated cGMP levels, but not cAMP, resulting in Cl^- and water secretion (Forte *et al.*, 1992). These effects appeared to be mediated by activation of PKA, as the T84 cells were devoid of the type II PKG. Support for this concept was obtained by measuring the endogenous activation of PKA. In a separate study by Cornwell *et al.* (1994b), treatment of cultured VSMC with interleukin 1β (IL- 1β) resulted in a large increase in cGMP due to the expression of iNOS. These increases in cGMP were associated with the inhibition of DNA synthesis *in vitro*. Similar to the study described above in T84 cells, the cultured VSMC were devoid of type I PKG. Both IL- 1β and

Table II Some Physiologically Important Substrates for PKG

Substrate ^a	Possible functions
VASP ^b	Focal adhesion assembly and integrin signal transduction in cells
Type V PDE ^c	Regulation of PDE activity in smooth muscle and other cells
Type I-IP ₃ receptor ^d	Modulate Ca^{2+} release from the SR of smooth muscle cells
Phospholamban ^e	Increase Ca^{2+} uptake into SR of smooth muscle cells
Thromboxane receptor ^f	Inhibit G-protein coupled IP ₃ formation in platelets
K _{Ca} channel α subunit ^g	K ⁺ efflux and hyperpolarize the smooth muscle cell membrane
Myosin binding subunit ^h	Modulate activity of myosin light chain phosphatase
HSP-20 ⁱ	Modulate contractility in smooth muscle cells
CFTR ^j	Activate Cl^- transport in rat intestinal epithelium
DARPP-32 ^k	Inhibit protein phosphatases in neural cells

high concentrations of NO-donor drugs activated PKA in these cells even though no increases in cAMP were observed. Hence, in two instances, large increases in cGMP were found to activate PKA in the intact cell. Whether this is a physiological event is not clear; nevertheless, these studies do illustrate the importance of examining the dose-response relationships of cyclic nucleotide "agonists" and cyclic nucleotide analogs when examining cellular responses.

Protein Kinase Inhibitors

It is a reasonable assumption that one of the more frustrating problems in defining a role for PKG (or PKA) in cell function is the lack of specific and pharmacologically well-characterized inhibitors (see Smolenski *et al.*, 1998, for extensive review on this subject). For the type I PKG, there are two classes of compounds that purportedly inhibit PKG with reasonable specificity and high affinity: the isoquinolinesulfonamide compounds and the phosphorothioates. The isoquinolinesulfonamides are believed to be competitive inhibitors for the binding of ATP to the catalytic site of the kinase, and are represented by the H compounds (e.g., H-8) and the KT compounds (e.g., KT 5823). The phosphorothioates, on the other hand, are competitive inhibitors of cyclic nucleotide binding, and are represented by the Rp stereoisomers of cGMP phosphorothioates (e.g., Rp-8-pCPT-cGMPS). When incubated with purified (or partially purified) kinases, KT 5823 and Rp-8-pCPT-cGMPS inhibit

enzyme activity with a 40-fold and 16-fold selectivity for PKG over PKA, respectively. On the other hand, the specificity of these two classes of compounds for inhibiting PKG in the intact cell is not impressive, and there are even reports that the KT compound does not inhibit PKG. In neutrophils (Wyatt *et al.*, 1991) and platelets (Smolenski *et al.*, 1998), KT 5823 was found to activate rather than inhibit PKG. These studies suggest that perhaps this compound is bio-transformed in some way to become an activator of PKG in some cells. Additionally, we reported that KT 5823 accumulates in aortic smooth muscle over a 30-min period to sufficient levels to inhibit PKA activity (Komalavilas and Lincoln, 1996). Clearly, this class of compounds has not been sufficiently characterized pharmacologically to rely on its use in intact cell studies. On the other hand, the Rp stereoisomers of cGMP have a more predictable effect in cells and tissues, but the specificity for inhibiting PKG over PKA is poor (Butt and Walter, 1996). The best outcome that can be expected in interpreting the data using this latter class of compounds is the ability to conclude that a cyclic nucleotide-dependent kinase, as opposed to other kinases, mediates a cell signaling event.

NO-Cyclic GMP Signaling in Vasodilation

Nitrovasodilator drugs such as nitroglycerine have been used clinically for more than a century in the treatment of angina. The mechanism involves peripheral vasodilation,

particularly venous vasodilation, which reduces the preload or end-diastolic volume of the heart. Preload reduction, in turn, decreases myocardial oxygen consumption, which is the basis of the effectiveness of the drug in angina therapy. It would be about 100 years before it was determined that cells make their own endogenous “nitrate,” that is, NO, and that a new era of vascular biology would be ushered in.

The role of cGMP in NO-induced vasodilation is clearly established from three major lines of evidence: (i) excellent correlative pharmacological evidence using NO-donor drugs and endogenous NO production to manipulate cGMP levels and relaxation in nearly all vascular tissue; (ii) the consistent findings that cGMP phosphodiesterase inhibitors and cGMP analogs mimic NO-dependent relaxation of various vascular smooth muscle preparations; and (iii) the effects of specific sGC inhibitors to block NO-mediated relaxation. Added to these observations is the study using PKG-I knockout mice, although as discussed later, there are some equivocal concerns with these latter studies.

Role of PKG in the Regulation of Intracellular Ca^{2+}

If the role of NO in vasodilation is clearly established, then the mechanism of action of cGMP and PKG seems less well defined. An early and consistent finding was that NO-donor drugs, cGMP analogs, and PKG (when introduced into smooth muscle cells) all lower intracellular Ca^{2+} levels, especially when elevated with a Ca^{2+} -mobilizing agonist (Cornwell and Lincoln, 1988, 1989; Johnson and Lincoln, 1985; Rashatwar *et al.*, 1987; Felbel *et al.*, 1988; McDaniel *et al.*, 1992; Meisheri *et al.*, 1986). Because Ca^{2+} is the major signal for the activation of myosin light chain (MLC) kinase and cross-bridge cycling in smooth muscle cells, these findings were of interest and significant. There are at least three major mechanisms by which PKG appears to lower intracellular Ca^{2+} in VSMC. First, PKG activates K_{Ca} channels, leading to hyperpolarization and an inhibition of voltage-dependent Ca^{2+} channels; second, it increases uptake of Ca^{2+} into intracellular stores; and third, it inhibits of hormone-dependent induced inositol monophosphate formation.

ACTIVATION OF K_{Ca} CHANNELS BY PKG

The smooth muscle K_{Ca} channel is composed of an α subunit, which is necessary for pore formation and is the actual component of the channel, and the β subunit, which is a regulatory protein for the channel (Tseng-Crank *et al.*, 1994). Activation of K_{Ca} channels by cyclic nucleotide-dependent protein kinases has been proposed to mediate relaxation (Hamaguchi *et al.*, 1991; Thornbury *et al.*, 1991; Kahn *et al.*, 1993; Chen and Rembold, 1996; Robertson *et al.*, 1993; Archer *et al.*, 1994; Sadoshima *et al.*, 1988). The two hypotheses that have been forwarded to account for the effects of PKG are (i) direct phosphorylation of the channel leading to activation (Sadoshima *et al.*, 1988; Kume *et al.*, 1989; Alioua *et al.*, 1995, 1998), and (ii) PKG-mediated dephosphorylation of the channel by activation of a protein phosphatase (White *et al.*, 1993; Zhou *et al.*, 1996). The evidence for the latter mechanism comes from studies using

inhibitors of the serine/threonine protein phosphatase, and particularly of protein phosphatase 2A (PP2A), to block the effects of PKG to activate K_{Ca} channels in either cultured pituitary cells (White *et al.*, 1993) or isolated smooth muscle cells (Zhou *et al.*, 1996).

If PP2A activation and subsequent dephosphorylation is the event that activates K_{Ca} channels, then the mechanism of PP2A activation is of paramount importance. The complexity of PP2A is impressive given the large number of genes and spliced variants of subunits expressed in different tissues, but basically the PP2A exists as a heterotrimer: a catalytic subunit, an A subunit generally considered to be a regulatory subunit, and a B subunit which is highly variable in expression and is thought to confer selective activity toward particular protein substrates (Kamibayashi *et al.*, 1994; Csontos *et al.*, 1996). None of the many forms of these subunits have been demonstrated to be phosphorylated by PKG in intact VSMC. It is conceivable that PKG might regulate association or translocation of PP2A to protein substrates such as the K_{Ca} channel in the cell, but this is pure speculation. A study by Zhou *et al.* (1998) seems to confirm the notion that the “biochemical properties” of a particular cell dictate whether cyclic nucleotide-dependent protein kinases are capable of regulating K_{Ca} channel activity. Neither PKA nor PKG affected the gating properties of transfected BK channel proteins in CHO cells, whereas both kinases inhibited gating of the channel in transfected myometrial cells. Given the complexity of the number of spliced variants of the K_{Ca} channel, and the importance of the phenotypic properties of cells expressing K_{Ca} channels, the regulation of K^{+} currents by cyclic nucleotides remains an area about which there is much to learn. To add further complexity to the situation, several studies now suggest that NO itself can directly activate BK channels in cells, possibly through a mechanism involving S-nitrosothiol formation (Krippeit-Drews *et al.*, 1992; Bolotina *et al.*, 1994; Lie *et al.*, 1992). The area of cGMP-independent regulation of cell function is a rapidly growing area of investigation as well (see section on cGMP and PKG-independent mechanisms of relaxation).

REGULATION OF SARCOPLASMIC RETICULUM Ca^{2+} BY PKG

It was demonstrated in the 1980s and 1990s that PKG-catalyzed phosphorylation of sarcoplasmic reticulum (SR) proteins, particularly the protein phospholamban (Vrolix *et al.*, 1988; Raeymaekers *et al.*, 1988; Sarcevic *et al.*, 1989; Karczewski *et al.*, 1992; Cornwell *et al.*, 1991; Murthy and Makhlof, 1995; Sulakhe and Vo, 1995; Sabine *et al.*, 1995). The importance of this finding was that some forms of the SR Ca^{2+} -transporting ATPases (known as SERCAs) are regulated by phosphorylation of phospholamban. On phosphorylation by either PKA or PKG at serine-16, or by Ca^{2+} -calmodulin-dependent kinase II at serine-17, phospholamban dissociates from the SERCA, thereby activating Ca^{2+} transport into the SR. Evidence that PKG catalyzes phosphorylation of phospholamban in the intact cell comes from studies demonstrating that (i) PKG-catalyzed phospholamban phosphorylation and activation of Ca^{2+} -ATPase occurs concomitantly with reductions in cytosolic Ca^{2+} (Vrolix

et al., 1988; Karczewski *et al.*, 1992; Cornwell *et al.*, 1991), and (ii) blockers of the SR Ca^{2+} -ATPase inhibit NO and cGMP-mediated Ca^{2+} reductions in smooth muscle (Luo *et al.*, 1993; Moritoki *et al.*, 1996; Andriantsitohaina *et al.*, 1995; Cohen *et al.*, 1999).

The importance of phospholamban phosphorylation in the regulation of smooth muscle relaxation *in vivo* has been questioned using studies on phospholamban-deficient mice. These animals demonstrate predictable prolonged cardiac relaxation and enhanced sensitivity of vascular smooth muscle to agonist-evoked contraction (Lalli *et al.*, 1997). On the other hand, the animals do not display impaired cardiac performance nor impaired vascular relaxation in response to NO-donor drugs (Lalli *et al.*, 1999). These results have been interpreted to suggest that phospholamban phosphorylation may play a relatively minor role in the regulation of cyclic nucleotide dependent relaxation.

There is other evidence, however, that phospholamban phosphorylation may be critical for K_{Ca} channel regulation. It has been shown by several laboratories that localized release of Ca^{2+} from the superficial SR located near the plasma membrane in smooth muscle triggers the activation of K_{Ca} channels (Stenho-Bittel and Sturek, 1992; Nelson *et al.*, 1995). The resultant hyperpolarization, termed spontaneous transient outward current or STOC, inhibits Ca^{2+} influx through voltage-dependent channels, which then produces a more global reduction in cytosolic Ca^{2+} . Porter *et al.*, (1998) have demonstrated that cAMP- and cGMP-elevating drugs increase STOCs from vascular smooth muscle cells through a mechanism dependent upon increased uptake and release of Ca^{2+} into the SR. In the phospholamban-deficient mice,

there were reduced STOCs in response to NO-donor drugs and forskolin, which resulted in a reduction in smooth muscle relaxation (Wellman *et al.*, 1999).

Based on the studies described in this section, a model illustrating the role of PKA and PKG in smooth muscle relaxation through phosphorylation and STOC generation is shown in Fig. 5. The differences between the *in vivo* studies where cyclic nucleotide-dependent relaxation appeared to be unimpaired (Lalli *et al.*, 1999) and the *in vitro* studies demonstrating impaired STOC generation and relaxation (Porter *et al.*, 1998; Wellman *et al.*, 1999) may be due to the development of embryonic compensatory mechanisms in the phospholamban deficient mice.

Another potential mechanism by which PKG increases STOCs in vascular smooth muscle is phosphorylation of the type I inositol 1,4,5-trisphosphate (IP_3) receptor in the SR. It has been shown that PKG catalyzes phosphorylation of the IP_3 receptor *in vitro* and in intact rat aorta (Komalavilas and Lincoln, 1994, 1996; Koga *et al.*, 1994), whereas other laboratories have demonstrated that PKA- and PKG-dependent phosphorylation of smooth muscle cell IP_3 receptors decreases Ca^{2+} release from the SR (Quinton and Dean, 1992; Murthy *et al.*, 1993; Cavallini *et al.*, 1996). On the other hand, IP_3 receptor phosphorylation by cGMP in hepatocytes appears to increase Ca^{2+} release (Enouf *et al.*, 1987; Bird *et al.*, 1993; Hajnoczky *et al.*, 1993; Rooney *et al.*, 1996). Part of the discrepancy of results may be due to different IP_3 receptor isoforms expressed in smooth muscle cells and hepatocytes. If IP_3 receptor phosphorylation leads to increased Ca^{2+} release from superficial SR, then this could trigger STOCs and decrease global cell Ca^{2+} , similar to the role of

Figure 5 Possible mechanisms of action of PKG on K^+ and Ca^{2+} currents in VSMC. PKG is known to catalyze the phosphorylation of the type I- IP_3 receptor (IP_3 R) and phospholamban (PLB) in the SR of VSMC. Depicted in the figure is the effect of PKG to activate Ca^{2+} uptake into the superficial SR, leading to a more robust release of Ca^{2+} through the IP_3 receptor channel and ryanodine receptor (RyR) channel. Phosphorylation of the IP_3 receptor may also lead to activation of Ca^{2+} release as well. The Ca^{2+} released into the submembrane space leads to activation of K^+ -activated Ca^{2+} channels (BK channels) in the plasmalemma (PL) (also known as STOCs) and hyperpolarization. Hyperpolarization decreases Ca^{2+} gating through the L-type Ca^{2+} channel and a decrease in global cell Ca^{2+} . PKG may also have direct effects to activate the BK channel and inhibit the Ca^{2+} channel.

PKG in increasing STOCs through phospholamban phosphorylation. A study by Makhoulf and colleagues also points to a cGMP, but PKG-independent role, in Ca^{2+} release (Murthy and Makhoulf, 1998a). Since cGMP interacts with multiple receptor proteins in the cell (e.g., cyclic nucleotide-regulated ion channels, cyclic nucleotide-regulated phosphodiesterases), it is conceivable that PKG-independent Ca^{2+} release is a component of the NO–cGMP signaling mechanisms in VSMC.

Alternatively, it is possible that IP_3 receptor function has little role in STOC generation in certain cells. Ryanodine-sensitive Ca^{2+} channels are clustered in the superficial SR of smooth muscle cells, raising the possibility that only ryanodine-sensitive Ca^{2+} release is critical for STOCs. Both PKA and PKG are known to catalyze phosphorylation of the ryanodine-sensitive Ca^{2+} channel *in vitro* (Suko *et al.*, 1993; Strand *et al.*, 1993; Mayrleitner *et al.*, 1995). There are no studies at this time, however, demonstrating a PKG-dependent phosphorylation of this channel in the intact smooth muscle cell. Therefore, at the present time, it is unclear whether phosphorylation of Ca^{2+} release channels in smooth muscle SR decreases intracellular Ca^{2+} levels through STOCs or through the inhibition of Ca^{2+} release from the SR. Perhaps both mechanisms operate in smooth muscle cells.

INHIBITION OF IP_3 FORMATION

There is a great deal of interest in the role of the NO–cGMP pathway in regulating phospholipase C and the generation of the second messengers IP_3 and diacylglycerol (DAG). In particular, because these second messengers mediate signal transduction in a variety of cells and tissues, demonstration of such regulation would provide a more widespread role for NO–cGMP signaling in regulating cell function. However, investigators have encountered some difficulty actually proving that this occurs. On the one hand, there are several literature citations showing that cGMP and PKG inhibit agonist-evoked increases in IP_3 formation (Rapoport, 1986; Takai *et al.*, 1981; Hirata *et al.*, 1990; Ruth *et al.*, 1993). Inhibition of IP_3 formation would surely provide a mechanism for the inhibition of agonist-evoked contraction of smooth muscle. On the other hand, the precise mechanism by which cGMP and PKG activation inhibit IP_3 or DAG formation is obscure.

Hofmann and co-workers (Ruth *et al.*, 1993; Pfeifer *et al.*, 1995) described the effects of PKG overexpression in Chinese hamster ovary (CHO) cells (normally PKG-deficient cells) on agonist-induced IP_3 formation. PKG activation was particularly effective in blocking thrombin-induced increases in IP_3 and intracellular Ca^{2+} release in CHO cells. These investigators proposed that PKG-mediated phosphorylation of the $\text{G}_{i\alpha}$ subunit in CHO cells was responsible for the inhibition of IP_3 formation (Pfeifer *et al.*, 1995). Despite the attractiveness of this hypothesis, PKG-dependent phosphorylation of $\text{G}_{i\alpha}$ *in vitro* was only observed using unusually high concentrations of kinase and substrate, and intact cell phosphorylation was reported to be relatively low. It is

known that protein kinase C (PKC) catalyzes phosphorylation of $\text{G}_{i\alpha}$ quite effectively *in vitro* and in the intact cell (Katada *et al.*, 1985), suggesting that the effects of PKG observed on $\text{G}_{i\alpha}$ phosphorylation are in reality PKC-like effects when the PKG is overexpressed.

An alternate explanation for PKG-mediated inhibition of IP_3 formation was proposed by Wong *et al.* (1998). In contrast to $\text{G}_{i\alpha}$, it is the thromboxane receptor from human platelets that is stoichiometrically phosphorylated using nanomolar concentrations of PKG *in vitro*, or 8-Br-cGMP in the intact cell. Peptide map analysis indicates that the phosphorylation site is within the cytoplasmic tail where G proteins interact with the serpentine receptor. In human platelets, G_q is the G protein that mediates thromboxane-induced IP_3 formation (Benka *et al.*, 1995). Thus, these data suggest that inhibition of G-protein signaling is indeed responsible for the effects of PKG in platelets, but the mechanism proposed in this case is receptor phosphorylation, not G-protein phosphorylation.

An intriguing study from Murthy and Makhoulf (1998b) suggests that phosphorylation and inhibition of phospholipase A_2 (cPLA₂) by PKG inhibits arachidonate- and IP_3 -dependent Ca^{2+} mobilization in smooth muscle. From these studies, it is reasonable to conclude, as illustrated in Fig. 6, that multiple mechanisms may be responsible for the inhibition of agonist-induced Ca^{2+} release in smooth muscle cells.

EFFECTS OF PKG ON Ca^{2+} CHANNELS

There have been numerous studies demonstrating cyclic nucleotide and protein kinase-mediated regulation of the activity of the L-type Ca^{2+} channel in cardiac myocytes (Wahler *et al.*, 1990; Mery *et al.*, 1991; Sumii and Sperelakis, 1995; Rotman *et al.*, 1995). In many cases, these effects may be related to K_{Ca} channel activation and subsequent hyperpolarization as described earlier. However, direct effects on myocyte L-type Ca^{2+} channels have also been reported. Most of these studies were conducted using cGMP analogs in either a whole-cell or an excised patch configuration. In some cases, purified PKG and catalytic subunit of PKA were applied to patches, and I_{Ca} currents were found to be affected (Sumii and Sperelakis, 1995).

If the physiological studies described above suggest an important role for PKG in regulating L-type Ca^{2+} channels, then there are no complementary biochemical studies outlining the mechanism by which PKG-dependent phosphorylation alters channel function. PKA has long been known to catalyze the phosphorylation of specific residues on the α subunit (pore-forming subunit) of the L-type Ca^{2+} channel (see e.g., Rotman *et al.*, 1995). In contrast, there have been no reports of specific PKG-mediated phosphorylation, although PKG catalyzes phosphorylation of sites phosphorylated by PKA *in vitro* (Jahn *et al.*, 1988). This does not necessarily suggest that PKG is incapable of specifically catalyzing the phosphorylation of channel subunits, but rather it alludes to the complexity of the Ca^{2+} channel biology in general. Adding to the complexity of the variability of L-type channel subunit expression in cells is the complexity

Figure 6 Possible mechanisms of action of PKG to inhibit intracellular Ca^{2+} increases in VSMC. Besides the generation of STOCs, PKG may have other actions to decrease intracellular Ca^{2+} . PKG inhibits the generation of IP_3 by inhibiting receptor coupling to heterotrimeric G proteins. Depicted in the figure are two potential mechanisms: first, the phosphorylation of serpentine-receptor intracellular domains involved in coupling to $\text{G}\alpha$ subunits, and second, the phosphorylation of the $\text{G}\alpha$ subunit itself. In either situation, the activation of phospholipase C (PLC) is inhibited, leading to decreases in the level of intracellular IP_3 . Other data suggest that the inhibition of cytosolic phospholipase A₂ (cPLA₂) by PKG-dependent phosphorylation may reduce arachidonic acid (AA) levels. Decreased AA may reduce Ca^{2+} release from the SR and decrease contractile protein sensitivity to intracellular Ca^{2+} .

of the cellular background in which the channel functions. In a remarkable study by Zong *et al.* (1995), neither PKA nor the protein kinase inhibitor peptide (PKI) affected L-type channel function when the subunits were expressed alone or in combination in CHO cells or human embryonic kidney (HEK) cells. This was in stark contrast to the effects of PKA in cardiomyocytes. Yet the selective PKA inhibitor H-89 attenuated channel function in CHO and HEK cells. Thus, the L-type Ca^{2+} channel is likely not to be modulated by cyclic nucleotide-dependent kinases in nonexcitable cells as it is in myocytes. The inhibitor studies also point out the likelihood that H-89 has other effects besides blocking PKA activity.

An interesting series of experiments by Keef and co-workers (Ishikawa *et al.*, 1993; Ruiz-Velasco *et al.*, 1998) suggests that cyclic nucleotides may have both opposing and similar actions on Ca^{2+} currents in smooth muscle cells, owing to the phenomenon of cross-activation. Low concentrations of cAMP analogs activate, whereas cGMP analogs inhibit, the I_{Ca} in VSMC. However, higher concentrations of cAMP inhibit Ca^{2+} channels through a mechanism that is blocked by the phosphorothioate PKG inhibitors. Therefore, cross-activation of cyclic nucleotide-dependent protein kinases appears to occur in at least a perforated patch-clamp model of smooth muscle cells.

The phenomenon of cross-activation described previously refers to the capacity of cAMP to activate PKG and

cGMP to activate PKA. Cross-activation, first suggested by Corbin and co-workers (Francis *et al.*, 1988; Jiang *et al.*, 1992), was demonstrated to function in isolated rat aortic smooth muscle cells deficient in PKG expression (Lincoln *et al.*, 1990). As suggested from the studies of Keef and co-workers, physiologically relevant concentrations of cAMP appear to be capable of activating PKG (Ruiz-Velasco *et al.*, 1998). Similar conclusions have been obtained by a number of laboratories examining specific physiological events (Murthy *et al.*, 1997; Eckly-Michel *et al.*, 1997; Kawada *et al.*, 1997). In contrast to these studies, cAMP had no effect to either lower Ca^{2+} or relax aortic tissue in the PKG-I null mice, suggesting that cross-activation does not occur under physiological conditions (Pfeifer *et al.*, 1998). However, it should be noted that the usual compensatory mechanisms that occur developmentally in response to gene ablation could occur, thereby masking an important physiological regulatory mechanism.

It is also important to note developmental differences in the regulation of Ca^{2+} channel activity by PKG. Kumar *et al.* (1997) have shown that in neonatal rabbit ventricular myocytes, cGMP activates rather than inhibits I_{Ca} . This effect appears to be mediated by PKG, which is highly expressed in neonatal myocytes compared with adult myocytes. In the adult myocyte, cGMP had little effect on I_{Ca} , neither increasing nor decreasing channel activity. There-

fore, it is important to consider the age of animals in conducting these types of studies, and this may be particularly relevant for cardiac myocyte work that relies heavily on the use of neonatal cells.

Perhaps the most novel mechanism proposed for the regulation of L-type Ca^{2+} channels by cGMP was based on a series of studies in the amphibian heart (Hartzell and Fischmeister, 1986; Mery *et al.*, 1993). In these studies, elevations in the level of cGMP inhibited the β -adrenergic Ca^{2+} current, whereas 8-Br-cGMP had no effect. Paradoxically, inhibitors of cyclic nucleotide phosphodiesterases (PDE) blocked the effects of cGMP rather than enhanced them. These investigators suggested that cGMP, by virtue of activation of a Type II PDE (cGMP-activated PDE), decreased cAMP levels, leading to a decrease in Ca^{2+} current. The importance of these findings is that cyclic nucleotides, and cGMP in particular, are capable of signaling cells through multiple receptor proteins (Lincoln and Cornwell, 1993). In fact, it has been shown that the complex expression of PDEs both activated by cGMP and inhibited by cGMP contribute to cGMP signal transduction in heart (Fischmeister and Hartzell, 1990) and other tissues (Somlyo and Somlyo, 1994). These studies also point out the caution that must be used in interpreting results based solely on the use of protein kinase inhibitors or PDE inhibitors in intact cells and tissues.

Role of PKG in the Regulation of Ca^{2+} Sensitization

An emerging area of research is the phenomenon known as “ Ca^{2+} sensitization” of contraction. Simply stated, Ca^{2+} sensitization is the capacity of contractile force to be developed in smooth muscle in the presence of diminishing concentrations of intracellular Ca^{2+} , or in the absence of increases in intracellular Ca^{2+} (reviewed in Somlyo and Somlyo, 1994). The technology for quantitating the concentrations of intracellular Ca^{2+} levels has markedly improved over the 1990s, as have the techniques for permeablizing smooth muscle tissue. As a result, investigators have consistently observed that agonist-induced contraction can be achieved in response to smaller increases in intracellular Ca^{2+} in comparison with depolarization-induced contraction. Furthermore, it is now clear that contractile activity, especially the generation of force without cross-bridge cycling, is achieved at near baseline cytosolic Ca^{2+} concentrations. These pivotal findings have led to the notion that low Ca^{2+} -requiring mechanisms exist to increase contractile force. There is now solid evidence that PKG plays an important role in regulating Ca^{2+} sensitization.

REGULATION OF MLC PHOSPHATASE

With respect to MLC phosphorylation, the incorporation of phosphate into serine-19 in the regulatory light chain of myosin is a result of the balance of activity between MLC kinase and MLC phosphatase. MLC kinase activity is governed principally by its activation by Ca^{2+} -calmodulin; little evidence exists that PKG actually catalyzes the phosphorylation of MLC kinase in the intact cell to inhibit it. MLC

phosphatase activity is governed principally by the binding of the catalytic subunit of the enzyme to smooth muscle myosin via a myosin-binding subunit (MBS). MBS is considered an anchoring protein for the phosphatase catalytic subunit, functioning both to bring the substrate (i.e., MLC) closer to the enzyme as well as to activate the phosphatase to dephosphorylate the substrate (see Hartshorne, 1998). Agonists decrease the activity of MLC phosphatase, possibly through a PKC-dependent phosphorylation of MBS (Masuom *et al.*, 1994). Although the detailed mechanism is not clear at this point, evidence suggests that the small GTP-binding protein Rho is involved in MLC phosphatase inhibition as well. It has been proposed that Rho activates a serine/threonine kinase, the *rho* kinase, to catalyze phosphorylation of MBS, resulting in the inhibition of the catalytic subunit (Gong *et al.*, 1996; Uehata *et al.*, 1997).

Other studies have shown that 8-Br-cGMP activates MLC phosphatase in arterial smooth muscle preparations (Lee *et al.*, 1997; Wu *et al.*, 1996). In these cases, PKG causes a Ca^{2+} desensitization of contraction, although the mechanism is unclear. It has also been speculated that cGMP and PKG could interfere with the *rho*-dependent activation of *rho* kinase, perhaps through the inhibition of the translocation of *rho* (or the *rho*-*rho* kinase complex) to the thick filaments (Somlyo and Somlyo, 1998). Related to these studies is the work of Surks *et al.* (1999) dealing with the potential targeting of PKG-I to MLC phosphatase. Using the yeast two-hybrid screen, these investigators have found that MBS is a major PKG-I anchoring protein in smooth muscle. PKG-dependent phosphorylation of MBS as a consequence of the association of the kinase with the subunit results in an activation of MLC phosphatase *in vitro*.

A different mechanism has been proposed by Somlyo and co-workers (Wu *et al.*, 1999). These investigators have shown that 8-Br-cGMP catalyzes the phosphorylation of the protein telokin in rabbit ileal smooth muscle. Telokin is a particularly abundant protein in this tissue and accelerates MLC dephosphorylation in permeablized strips. Thus, telokin phosphorylation by PKG represents a novel and potentially important mechanism for regulating Ca^{2+} desensitization of contraction. Thus, there may be multiple mechanisms by which PKG regulates Ca^{2+} sensitization of contraction of smooth muscle.

THIN FILAMENT REGULATION BY PKG

From the discussion above, it is evident that phosphorylation of MLC has been a major focus of Ca^{2+} sensitization mechanisms in smooth muscle. There are also data demonstrating that Ca^{2+} -independent contraction of smooth muscle occurs in the absence of MLC phosphorylation, suggesting a thin filament-dependent regulation of smooth muscle contraction. Proteins that regulate smooth muscle contractility in this fashion include the thin filament-binding proteins caldesmon and calponin. Phosphorylation of both proteins are known to occur in the intact cell, but no role of the NO-cGMP-PKG signaling pathway in thin filament regulation has been established.

VASP AND HSP-20

Of the growing number of proteins whose phosphorylation is increased in response to PKG activation in the intact cell, and perhaps the best characterized, is the actin-binding protein VASP (vasodilator-stimulated phosphoprotein). In addition to actin, VASP binds to cytoskeletal proteins such as profilin and vinculin at the focal adhesion junction of cells. The role of VASP in platelet function, focal adhesion formation, and cell motility has been reviewed by Walter and colleagues (Eigenthaler *et al.*, 1998). Although VASP is expressed in practically every cell type examined, the physiological role of VASP may be best characterized in platelets. Phosphorylation of VASP by PKA and PKG on different sites results in the inhibition of integrin α_{IIb} activation (Horstrup *et al.*, 1994; Eigenthaler and Shattil, 1996). This may be an important mechanism involved in the inhibition of platelet aggregation and adhesion, known to be affected by NO donor drugs. A potentially interesting clinical model of the role of PKG and VASP is human chronic myelocytic leukemia (CML) where PKG expression in platelets is virtually absent (Eigenthaler *et al.*, 1993). Patients with CML demonstrate impaired NO-dependent signal transduction in platelets.

The role of PKG in the regulation of cellular adhesion, migration, and motility is still an area ripe for investigation. There have been several studies published regarding the role of NO and the cGMP signal transduction system in leukocyte migration and degranulation (Pryzwansky *et al.*, 1995a; Wyatt *et al.*, 1993; Elferink and de Koster, 1993; Elferink and Van Uffelen, 1996), but few studies have been directed toward understanding the biochemical mechanisms involving PKG in these physiological processes. In one study on the regulation of focal adhesion formation, activation of PKG was required for matrix protein-dependent focal adhesion disassembly in endothelial and vascular smooth muscle cells (Murphy-Ullrich *et al.*, 1996). Given the potential importance of the cGMP-PKG signaling pathway in the regulation of VSMC growth, migration, and phenotypic expression (see section on cyclic GMP and VSMC phenotypic modulation), it is likely that the elucidation of these processes will increase our understanding of the role of this pathway in vascular diseases.

As mentioned earlier, many of the proteins described as physiological substrates for PKG are uncharacterized. Some of these are relatively small molecular weight entities (i.e., 20–30 kDa) and have been known for some time to be potential substrates for PKG (Rapoport *et al.*, 1982; Li *et al.*, 1996). One such protein has been identified as heat-shock protein 20 or HSP-20 (Beall *et al.*, 1997). Although the precise role of HSP-20 in smooth muscle contraction is unknown, HSP-20 phosphorylation may play a critical role in NO-cGMP-dependent relaxation. HSP-20 is phosphorylated in response to PKA- or PKG-dependent activation in bovine trachealis and carotid artery. Moreover, HSP-20 phosphorylation does not occur in human umbilical artery smooth muscle, a tissue which is insensitive to relaxation by

cyclic nucleotides (Bergh *et al.*, 1995; Brophy *et al.*, 1997). These results indicate that HSP-20 may play a role in the regulation of contractile activity in smooth muscle, such as that of regulating myosin phosphorylation or perhaps thin filament function. Clearly more research is needed in this area.

cGMP and PKG-Independent Mechanisms of Relaxation

As is often the case with emerging areas of research, the more scrutiny a topic receives, the more issues arise which at the very least prove to be “exceptions to the rule.” In the case of cGMP and PKG-dependent vasodilation in response to NO, there are now reports of NO-dependent and cGMP-independent mechanisms of vasodilation. On the one hand, such reports should hardly be unexpected, as the number of reported cGMP-independent actions of NO seems to be growing faster than those events mediated by cGMP. On the other hand, the importance of cGMP and PKG in vasorelaxation must surely be appreciated based on the published effects of the sGC inhibitor, ODQ (1*H*-[1,2,4]oxadiazolo-[4,3-*a*]quinoxalin-1-one), to block NO-dependent relaxation (Moro *et al.*, 1996) and the effects observed in the PKG-null mice (Pfeifer *et al.*, 1998). The most plausible statement that can be made at this time is that there exist some cGMP-independent actions of NO with regard to cellular function; nevertheless, the exquisite sensitivity of sGC to stimulation by NO indicates that the cGMP-PKG pathway remains a major signaling mechanism for NO in cells.

With regard to cGMP-independent vasorelaxation, Cohen and co-workers (Weisbrod *et al.*, 1998) have identified a cGMP-independent decrease in intracellular Ca^{2+} levels associated with relaxation in the rabbit aorta. This effect may be due to the activation of K_{Ca} channels by NO reported earlier by this laboratory (Bolotina *et al.*, 1994). In a similar vein, Roman and colleagues have demonstrated that NO-dependent vasodilation in renal arteries is not blocked by sGC or PKG inhibitors, but is sensitive to inhibition of P-450 epoxygenase (Sun *et al.*, 1998; Alonso-Galicia *et al.*, 1998). Despite the reservations concerning interpretation of data using inhibitors alone, these results suggest that the inhibition of 20-HETE by NO, in part at least, mediates the vasodilatory effects of NO in these vessels. The attractiveness of this hypothesis lies in the fact that the effects of NO are due to direct binding to the heme moiety of the P-450 epoxygenase. As alluded to earlier, heme-containing enzymes and proteins act as “receptors” for NO in a manner analogous to sGC. Because the affinity of sGC for NO is high (nanomolar), and it has yet to be determined whether the affinity of all the other heme-containing proteins for NO is equally as high, it may be premature to speculate that all heme-containing proteins are receptors for NO. Nevertheless, it is an attractive idea that the diversity of NO signaling may be based on the diversity of heme-containing receptor proteins for NO.

Other possible cGMP and PKG-independent actions of NO in vascular and other tissue is based on S-nitrosothiol formation. S-Nitrosation has been known since the 1970s from the earlier studies involving NO-donor drug action (Eiserich *et al.*, 1994). There is a great deal of interest in the fact that NO may be both stored as an S-nitrosothiol in cells and form S-nitrosothiols with proteins to regulate their function (Davisson *et al.*, 1996). However, direct measurement of physiologically important S-nitrosothiols in response to NO production is lacking in most studies. Furthermore, because NO activates signaling pathways at nanomolar concentrations, one might not expect to be able to measure generalized S-nitrosation of proteins in cells.

Despite the lack of direct evidence for S-nitrosothiol signaling for NO, indirect studies suggest that such specific and sensitive effects of NO occur in response to physiological levels of NO. In cultured VSMC, physiological concentrations of NO induce the expression of the mRNA for glutamylcysteine synthetase (GCS) (Moellering *et al.*, 1998). Importantly, these cells lack PKG, and the effects of NO were neither blocked by ODQ nor mimicked by 8-Br-cGMP. Although the mechanism of the effect of NO is unknown at this point, it is conceivable that nitrosation of some specific cellular component or nitration by NO-derived reactive nitrogen species leads to increased rates of transcription of the GCS gene.

Just how widespread are cGMP/PKG-independent effects of NO in cells? From the pathophysiological point of view, it is clear that cytokine-evoked NO production through iNOS expression could regulate protein function through several mechanisms such as the generation of S-nitrosothiols or peroxynitrite. Are physiologically relevant levels of NO capable of regulating cellular function through mechanisms similar to these? To begin to address this question, it may be beneficial to recall one of the basic tenets of intracellular signaling, namely, amplification. The attractive feature of the second messenger hypothesis proposed in the 1950s is that it is amplification of extracellular signals through intracellular enzymatic catalysis that allows minute concentrations of such signals to alter cell function in a specific and efficient manner. sGC activation by NO meets the criterion for amplification; unfortunately, there are only a few other instances in the NO signaling literature which do. In some reports, the levels of NO used in cell signaling experiments are not evaluated for potential physiological significance. Furthermore, the effects of high concentrations of NO on cells may be due to the mere stoichiometric interaction of NO with cellular effector molecules that are not intracellular catalysts. The amplification of signals necessary for specific, reversible, and efficient alterations in cellular function is therefore absent. From a pathophysiological point of view, stoichiometric (as opposed to catalytic) effects of NO may well be significant. From the standpoint of establishing experimental protocols to study the physiological role of NO in cellular function, however, it is important for the experimentalist to approximate the physiologically relevant condition.

Studies Based on PKG Null Mice

Both forms of PKG have been genetically ablated through gene targeted disruption (Pfeifer *et al.*, 1996, 1998). For PKG-II, the phenotypes were more surprising, perhaps because less is known about the biological role of PKG-II. The major physiological disruptions in the PKG-II null mice were reported to be stunted growth and impaired intestinal secretion (Pfeifer *et al.*, 1996). Impaired intestinal secretion in response to *Escherichia coli* enterotoxin and guanylin is a predicted phenotype based on the findings of DeJonge and co-workers that type II PKG catalyzes the phosphorylation and activation of the Cl⁻ transporter, the cystic fibrosis transmembrane conductance regulator or CFTR, in the basal membranes of intestinal epithelial cells (Vaandrager *et al.*, 1997). However, the dwarfism produced in response to type II PKG deficiency was an unexpected phenotype. Subsequently, these authors demonstrated a high level of expression of PKG-II in chondrocytes in developing bone. Thus, PKG-II appears to play a central role in endochondral ossification at the growth plates.

In contrast to the unpredicted phenotypes of the PKG-II null mice, PKG-I null mice were shown to have ablated NO-dependent vasodilation in aortic VSMC (Pfeifer *et al.*, 1998). Additionally, conscious mice had elevated mean arterial blood pressure (MAP) and reduced vasodilation to NO. And finally, a most dramatic phenotype of the PKG-I null mice was impaired intestinal motility arising from the absence of NO- and cGMP-mediated intestinal smooth muscle relaxation. Overall, these phenotypic differences between PKG +/+ and PKG -/- were predictable based on the known role of the cGMP-PKG pathway in mediating smooth muscle relaxation, and based on the studies reporting deficient vasorelaxation in endothelial NOS (eNOS) (Huang *et al.*, 1995) and atrial natriuretic peptide (ANP) receptor (Lopez *et al.*, 1995) null animals.

There were some unusual findings, however, in the PKG-I null animals that warrant further study. In the first instance, half the animals died of unspecified causes between 35 and 40 days. The effects of PKG ablation on MAP seemed to be confined to animals that were under 32 days of age, because older animals (42 days) were normotensive. Furthermore, even the younger PKG-I null animals when anesthetized did not demonstrate differences in MAP from wild-type animals. It should be noted that even a 42-day-old animal is a juvenile, so that ablation of the PKG-I gene had an apparent lethal effect by a mechanism that was not addressed. And finally, the authors observed that adenosine A2 receptor agonists and cAMP analogs relaxed aortas from the PKG-I null mice in a normal fashion. Although the authors suggested this was evidence against cAMP-dependent cross-activation of PKG, it is more likely that compensatory mechanisms coupled with the lethality of the gene ablation were responsible for the effects of cAMP in the pathologically generated animal. As is always the case with embryonic stem cell mutants, developmental patterns shift to compensate for loss of gene products, and these compensatory mechanisms must be factored into the resultant phenotype.

The Uterus: A Paradox for the NO–cGMP Model for Vasorelaxation

During the early days of discovery in the NO–cGMP field, there were persistent reports that NO-donor drugs and cGMP analogs failed to produce smooth muscle relaxation. The scientific meetings where these findings were presented and heatedly debated made for wonderful entertainment, but the fact is that some smooth muscle tissues are indeed quite refractory to NO-dependent relaxation. The focal point of the controversy was the lack of relaxation of uterine smooth muscle to NO and cGMP.

An early and definitive study on the role of cGMP in mediating NO-dependent relaxation in nonvascular smooth muscle was done by Diamond (1983). In contrast to vascular smooth muscle and gastrointestinal smooth muscle, uterine smooth muscle was refractory to NO-dependent relaxation despite the fact that the drugs utilized elevated cGMP levels. The refractoriness of uterine smooth muscle was a particularly interesting finding, as Word *et al.* (1991) later demonstrated that cGMP decreased intracellular levels of Ca^{2+} and inhibited myosin light chain phosphorylation in human uterine smooth muscle cells.

Other studies have again raised the issue of NO-mediated uterine smooth muscle relaxation. Yallampalli and colleagues (1993, 1994) have published new studies suggesting that relaxation of the uterus by NO and cGMP analogs is particularly sensitive during pregnancy. At first glance, these findings are attractive because (i) they may relate the variable effects of NO and cGMP on relaxation to the hormonal status of the animal, and (ii) they may provide a biochemical mechanism underlying uterine quiescence during pregnancy. However, other laboratories (Bek *et al.*, 1998; Potvin and Varma, 1990; Word and Cornwell, 1998) have found just the opposite effects of pregnancy and hormonal status on uterine sensitivity to NO. In these later studies, uterine smooth muscle from pregnant animals was completely refractory to relaxation by NO, cGMP analogs, or natriuretic peptides when compared to tissue from nonpregnant animals. This was despite the capacity of the NO-donor drugs and the peptides to increase cGMP levels. A mechanism for the greater insensitivity of uterine tissue to relaxation by NO and cGMP from pregnant animals was proposed by Word and Cornwell (1998). These investigators found that progesterone inhibits, whereas estradiol increases, the expression of PKG in uterine smooth muscle cells. These studies were extended to and confirmed in human uterine smooth muscle cells (Cornwell and Word, 1994). Therefore, the role of NO and cGMP in the relaxation of uterine smooth muscle still remains unresolved. Most evidence, however, suggests that the NO–cGMP pathway does not mediate uterine smooth muscle relaxation. This of course begs the question: What is the role of the NO–cGMP pathway in uterine smooth muscle? A new role for cGMP and PKG in regulating smooth muscle cell phenotype is emerging (see section on cyclic GMP and VSMC phenotypic modulation). Because uterine smooth muscle undergoes dramatic phenotypic changes depending

on the hormonal status of the animal, it is possible that the NO-signaling pathway plays a key role in regulating gene expression during phenotypic transitions in this tissue.

NO–Cyclic GMP Signaling in Vascular Disease

Vascular disorders including atherosclerosis, peripheral occlusive disease, restenosis following angioplasty and transplantation, and hypertension all fall under the umbrella of vascular disease. The single most significant underlying pathology associated with vascular disorders arising from injury is that the VSMC acquire a fibroproliferative phenotype *in vivo*, which leads to the “remodeling” of the vessel wall (see Ross, 1993, for a review). As a result, blood flow is usually reduced, with an accompanying increase in wall stress, platelet activation, and leukocyte extravasation. The physiological mechanisms regulating the “switch” that controls the modulation from the muscle phenotype to the fibroproliferative phenotype are unknown, but there is an emerging awareness of the importance of cGMP and PKG in controlling VSMC phenotype.

VSMC Phenotypic Modulation

It has been known since the 1980s that when certain VSMC are placed in culture and grown in medium supplemented with serum-derived growth factors, the cell phenotype changes from one expressing contractile proteins (the contractile phenotype) to one expressing extracellular matrix proteins or ECM (the synthetic phenotype) (Chamley-Campbell *et al.*, 1979, 1981; Hedin *et al.*, 1990; Rovner *et al.*, 1986). The same phenotypic changes occur in the medial layer VSMC in the vessel wall in response to various injury (Campbell and Campbell, 1985; Gown *et al.*, 1986; Majesky *et al.*, 1992; Mosse *et al.*, 1985). This is because the VSMC represent the primary “wound-healing” cells in the vessel wall, and they must be able to undergo a change in function from that of regulating the diameter of the lumen of the vessel to repairing the vessel when injured. In culture, as *in vivo* in response to injury, VSMC suppress the expression of the unnecessary contractile proteins and increase the production of ECM proteins such as collagen, fibronectin, osteopontin, and thrombospondin. A variety of growth factors and inflammatory mediators in the vessel wall including platelet-derived growth factor (PDGF), fibroblast growth factor (FGF), insulin-like growth factor (IGF), and various cytokines such as IL-1 β , tumor necrosis factor α (TNF- α), and γ -interferon (IFN- γ) are believed to promote phenotypic modulation to the synthetic state. It will be recognized that these are typical biological responses, that is, inflammatory responses, to injury.

Cyclic GMP and VSMC Phenotypic Modulation

NO and natriuretic peptides have been shown to inhibit VSMC proliferation both *in vitro* and *in vivo* (Johnson *et al.*,

1988; Abell *et al.*, 1989; Garg and Hassid, 1989a,b; Appel, 1990; Kariya *et al.*, 1989; Nakaki *et al.*, 1990a; McNamara *et al.*, 1993; Cayatte *et al.*, 1994; De Meyer *et al.*, 1995; van der Leyen *et al.*, 1995). With regard to the *in vivo* studies, it has not been clear whether these effects are due to direct actions on VSMC proliferation in the vessel wall or are due to indirect effects such as inhibiting platelet activation and leukocyte infiltration. Indeed, in a broad clinical trial examining the effects of NO-donor drugs on patients following percutaneous transluminal coronary angioplasty (PTCA), there were no impressive protective effects of the drugs in preventing restenosis (Lablanche *et al.*, 1997).

There are also problems in interpreting the effects of NO donor drugs on VSMC proliferation *in vitro*: first, the majority of these studies had been performed on multiply passaged cells, usually of adult rodent origin, that were already in the synthetic phenotype and do not express high levels of PKG. Second, and related to this problem, only high micromolar concentrations (usually $>100 \mu M$) of NO-donor drugs such as SNP or SNAP were effective in inhibiting adult VSMC proliferation. These questions raise the issues of whether the effects of NO are mediated via the cGMP–PKG pathway and whether they are physiologically relevant. And finally, Hassid *et al.* (1994) have shown that the effects of NO on VSMC proliferation are dependent on the phenotype of the

cell; thus, NO inhibits the proliferation of VSMC in the synthetic phenotype at concentrations described above, but lower concentrations of NO stimulate the proliferation of VSMC in the contractile phenotype.

Studies have begun to address the role of NO and cGMP in the regulation of VSMC phenotype and proliferation (Boerth *et al.*, 1997; Cornwell *et al.*, 1994b; Dey *et al.*, 1998; Lincoln *et al.*, 1998). Because rat aortic SMC that have been routinely passaged several times *in vitro* cease to express measurable quantities of PKG, an examination of the effects of PKG restoration to cells deficient in the enzyme were made possible. PKG-I α , or the catalytically active domain of PKG-I (Boerth and Lincoln, 1994), caused the synthetic cells to resume the contractile morphology (Boerth *et al.*, 1997). As shown in Fig. 7, the PKG-expressing cells become spindle-shaped and grow in the “hill and valley” appearance typical of primary cultures of VSMC at confluence. In contrast, the PKG-deficient cells remain fibroblastic in appearance and grow in irregular arrays *in vitro*. Importantly, the expression of biochemical markers for the contractile phenotype (e.g., smooth muscle myosin heavy chain, calponin, desmin, α -actinin) are restored in only the PKG-expressing cells (Boerth *et al.*, 1997), whereas PKG suppresses biochemical markers for the synthetic phenotype (e.g., osteopontin and thrombospondin) (Dey *et al.*, 1998). Thus, it

Figure 7 Effect of PKG expression on VSMC morphology. Rat aortic VSMC stably transfected with vector alone (A and C) or with vector containing the PKG catalytic domain (B) or the PKG-I α holoenzyme (D) were photographed 96 hours after plating. In E and F, cells were treated with or without $1 \mu M$ forskolin to activate PKA in PKG-deficient cells. Note the contractile-like morphology displayed by cells expressing PKG or the catalytic domain of PKG compared to the synthetic morphology displayed by cells deficient in the expression of PKG. Note also the lack of effect of cAMP on cellular morphology. [From Lincoln *et al.* (1998). *Acta Physiol. Scand.* **164**, 507–515. Reprinted with permission from the Scandinavian Physiological Society.]

appears that at least one mechanism regulating phenotypic modulation involves the expression of PKG.

The mechanisms regulating PKG-I expression were discussed earlier. Of particular interest for its role in VSMC phenotypic modulation is the potential role of inflammation in suppressing PKG expression. It is well established that mechanical injury, or chronic injury due to oxidative stress and atherosclerosis, leads to an inflammatory response characterized by the activation of leukocytes and other inflammatory cells in the vessel wall (Libby and Galis, 1998, for a review). Hence, immunoreactive IL-1 β , TNF- α , and IFN- γ have been shown to be present in vascular lesions. One of the major gene products known to be expressed in response to inflammatory cytokine action is iNOS (Beasley and Eldridge, 1994), and in fact iNOS is robustly expressed in immune cells and VSMC in atherosclerotic and restenotic lesions (Yan and Hansson, 1998). A temporal correlation following iNOS and PKG expression in swine coronary arteries following balloon catheter injury has been performed, demonstrating that iNOS expression increases prior to the suppression of PKG expression in the lesions (Anderson *et al.*, 1996). Additionally, NO-donor drugs and inflammatory cytokines suppress PKG expression in primary cultures of bovine aortic SMC (Soff *et al.*, 1997; Lincoln *et al.*, 1998). Together, these findings support the concept that persistent elevations in NO production suppress PKG expression. This has led to the proposal that one mechanism linking inflammation in response to injury to alteration in cell phenotype, leading to subsequent wound-healing activity and vessel wall remodeling, is the suppression of PKG expression (Soff *et al.*, 1997; Boerth *et al.*, 1997; Cornwell *et al.*, 1994b; Dey *et al.*, 1998; Lincoln *et al.*, 1998). It is predictable that one active area of future research will be which factors control PKG expression—both up and down—in the vessel wall.

Cyclic GMP and Cell Growth

GENE EXPRESSION

From the previous discussion, it is clear that a potentially important role exists for cGMP and PKG in the regulation of gene expression in vascular cells. The first suggestions that cGMP regulates gene expression came from studies in PC12 cells demonstrating that NO and cGMP enhanced Ca²⁺-dependent regulation of the *c-fos* promoter (Peunova and Enkolopov, 1993; Haby *et al.*, 1994). Subsequent to these findings, Pilz, Boss, and co-workers have established that transfection of cDNAs encoding PKG-I β into baby hamster kidney (BHK) cells lacking the kinase results in a cGMP-mediated activation of the *c-fos* promoter (Pilz *et al.*, 1995; Gudi *et al.*, 1996, 1997; Idriss *et al.*, 1999). The mechanism appears to be mediated by several sequence elements, including the serum response element (SRE), the AP-1 site, and the cAMP response element (CRE) (Gudi *et al.*, 1996; Idriss *et al.*, 1999). The latter element is of considerable interest because several pathways, namely, PKA, Ca²⁺-calmodulin kinase II, and PKC, lead to activation of the CRE. Phosphorylation of the CREB protein by PKG *in vitro*

has in fact been reported, but the effectiveness of PKG compared to PKA is low (Colbran *et al.*, 1992). It is therefore unlikely that CREB is a physiologically relevant target for PKG. It is more likely that PKG catalyzes the phosphorylation of a unique CRE-binding protein that interacts alone or in combination with CREB proteins.

An interesting role for translocation of PKG to the nucleus to regulate gene expression has been suggested. Pryzwansky *et al.* (1995b,c) first had reported the presence of PKG immunofluorescence in the nucleus of neutrophils and monocytes, but the mechanism by which PKG might be localized there was unknown. Studies by Gudi *et al.* (1997) using site-directed mutation of a putative IL- α like nuclear localization sequence (NLS), consisting of amino acids 404–411 in PKG-I β (KILKKRHI), prevented PKG from translocating into the nucleus of BHK cells. In the absence of nuclear translocation, PKG was unable to activate *c-fos* promoter activity. These studies suggest a role for PKG in nuclear protein phosphorylation comparable to the role of the catalytic subunit of PKA. In the latter case, however, translocation of the C subunit appears to be controlled by the protein kinase inhibitor protein which acts as a “chaperon” to export the C subunit from the nucleus (Harootunian *et al.*, 1993; Wen *et al.*, 1994). For PKG, the mechanisms responsible for PKG exporting the nucleus—if they exist—are unknown. More recently, the role of nuclear translocation of PKG to regulate gene transcription has been questioned (Collins and Uhler, 1999). In the latter study, the holoenzyme of PKG was not translocated to the nucleus on activation by cGMP, and the level of gene transcription using a transfected CRE promoter was exceedingly low compared with PKA. On the other hand, the active catalytic domain of PKG appeared to localize in both the cytoplasm and nucleus of cells due to its smaller size. Overall, these findings support the concept of Harootunian *et al.* (1993) and Wen *et al.* (1994) suggesting the need for a chaperon for PKG if, in fact, its translocation to the nucleus is required for the regulation of gene expression. The mechanisms of gene regulation by PKG will likely be an important issue for further study since import and export from the nucleus is necessary to establish the physiological importance of the translocation event.

GROWTH

Regulation of *c-fos* gene expression is obviously one potential mechanism wherein PKG may regulate growth and differentiation of cells. As discussed earlier, the role of PKG in cell proliferation is highly controversial. Moreover, as *c-fos* gene expression is almost invariably associated with increased cell growth and proliferation, the molecular studies on gene expression do not shed new light on the role of PKG in cell proliferation.

In multiply passaged rat aortic SMC lacking PKG, Cornwell *et al.* (1994b) reported that high concentrations of NO-donors and IL-1 β (which induces iNOS in the cells) inhibited PDGF-induced proliferation. The mechanism was apparently related to the effect of cGMP to cross-activate

PKA. Cyclic AMP and PKA activation have long been known to inhibit VSMC proliferation (Fukumoto *et al.*, 1988; Jonzon *et al.*, 1985; Loesberg *et al.*, 1985; Morisaki *et al.*, 1988; Nakaki *et al.*, 1990b; Souness *et al.*, 1992; Southgate and Newby, 1990). In VSMC differentiated to the contractile phenotype by PKG, there were no substantial effects of cGMP on proliferation of the cells (Boerth *et al.*, 1997). These studies support those of Hassid and co-workers (1994), where treatment of primary cultures of adult rat aortic SMC still expressing PKG did not effect proliferation. On the other hand, the proliferation of neonatal aortic SMC that still express PKG but retain a synthetic phenotype was inhibited by low concentrations of NO and cGMP (Hassid *et al.*, 1994). In a study by Chiche *et al.* (1998), it was reported that when passaged pulmonary artery VSMC lacking PKG were transiently transfected with PKG using adenoviral constructs, NO and cGMP dramatically reduced proliferation. These authors concluded that PKG mediates the antiproliferative effects of NO and cGMP in VSMC. One possible explanation for the differences between the effects reported by Boerth *et al.* (1997) and Hassid *et al.* (1994), on the one hand, and Chiche *et al.* (1998), on the other, was the phenotype of the cells. The pulmonary arterial cells infected by adenoviral PKG appeared to be synthetic in phenotype; according to the work of Hassid *et al.* (1994), activation of the NO pathway and PKG would be predicted to inhibit proliferation of cells in this phenotype. The issue of the physiological role of NO, cGMP, and PKG in the regulation of VSMC proliferation is likely to remain controversial, owing to the differential effects of NO and cGMP in cells displaying different phenotypes, the lack of reliable inhibitors to affect PKG, and the ability of the cAMP and cGMP pathways to cross and converge at multiple sites.

MAP KINASES

One of the most widely studied pathways leading to altered growth and proliferation of cells is the mitogen-activated protein kinase (MAP kinase) pathway. There are numerous reviews regarding the components of this pathway, and these will not be recalled here. One thing that is clear from the mountain of evidence generated to date is that the activation of the MAP kinase pathway, and specifically the extracellular regulated kinase or ERK pathway, is necessary for *c-fos* gene expression (Karin, 1994). However, the only reported studies regarding the potential role of cGMP and PKG in regulating the MAP kinase pathway seem to suggest an inhibitory role for cGMP and PKG in regulating ERK activity (Yu *et al.*, 1997; Suhasini *et al.*, 1998). However, there are some possible explanations for these findings when the data are examined in light of the nuances regarding inhibitor studies and the overlapping substrate specificity noted for the cyclic nucleotide-dependent protein kinases.

In one of the first studies conducted to define the role of PKG in regulating the ERK pathway, Yu *et al.* (1997) examined the effects of the KT class of inhibitors on ERK activation in passaged VSMC. On the basis of the actions of these inhibitors, these authors concluded that NO and cGMP,

through PKG activation, inhibit ERK activation. The mechanism was proposed to involve the phosphorylation of Raf-1 by PKG since purified PKG catalyzed phosphorylation of Raf-1 in an *in vitro* assay. A similar conclusion was reached by Suhasini *et al.* (1998) using the BHK cell system. These cells are devoid of PKG, so that stable transfection of the kinase into the cells may be used to specifically examine the effects of PKG on cell pathways. In this study, cGMP analogs inhibited ERK activation, and PKG inhibitors reversed these effects. Furthermore, Raf-1 was phosphorylated on serine-43 in the intact BHK cell in response to cGMP in the PKG-expressing cells only. Both papers suggested that a physiologically relevant role of PKG is the phosphorylation of Raf-1 on serine-43, resulting in the inhibition of Ras binding and ERK activation.

There are unanswered questions regarding these studies, however; in the first instance, Raf-1 is a physiologically relevant substrate for PKA, and numerous studies have shown that activation of the PKA pathway results in the phosphorylation of serine-43 on Raf-1 and the inhibition of ERK activation by this mechanism (Graves *et al.*, 1993; Wu *et al.*, 1993; Chuang *et al.*, 1994; Hafner *et al.*, 1994; Erhardt *et al.*, 1995; Kikuchi and Williams, 1996; Mischak *et al.*, 1996; Faure and Bourne, 1995; Yee and Worley, 1997). Furthermore, PKA, but not PKG, is a potent catalyst for the phosphorylation of serine-43 on Raf-1 *in vitro* (T. M. Lincoln and P. Komalavilas, 1998, unpublished). Because it is known that PKG will catalyze phosphorylation of known PKA substrates in cells under appropriate conditions (Lincoln and Cornwell, 1993; Lincoln, 1994; Lincoln and Corbin, 1997, 1983), it is possible that overexpression of PKG in BHK cells has resulted in the activation of this kinase to mimic the more physiologically important effects of PKA on Raf-1 phosphorylation. Because neither study examined the effects of agents that elevate cAMP or cAMP analogs on Raf-1 and ERK activation, it cannot be concluded that the results reported are specific, physiologically relevant effects of PKG activation.

It is also known that phenotypically contractile smooth muscle cells express abundant ERK that is tonically in a relatively activated state (Khalil and Morgan, 1993; Adam *et al.*, 1995; Dessy *et al.*, 1998; Mii *et al.*, 1996; Menice *et al.*, 1997). The role of ERK in contractile smooth muscle function is a subject of much investigation (Adam *et al.*, 1995; Dessy *et al.*, 1998; Gorenne *et al.*, 1998), but it is clearly activated during contraction and not associated with proliferation. In contractile VSMC that express PKG, ERK activity is relatively high compared with synthetic VSMC that are deficient in PKG (Fig. 8). It would appear, therefore, that like the effects of cGMP on proliferation, the effects of NO–cGMP on ERK activity may depend very much on the phenotype of the VSMC. It is likely that in phenotypically contractile VSMC, ERK activity is relatively high as a result of PKG expression. ERK activation by PKG provides a plausible mechanism for *c-fos* promoter activation by PKG. Because *c-fos* expression is one hallmark of increased proliferative capacity of cells, the growth-promoting effects of

Figure 8 Effects of PKG expression on MAP kinase activity in cultured VSMC. Rat aortic VSMC stably transfected with vector alone (designated by PKG -) or with vector containing PKG- α holoenzyme (designated by PKG +) were treated with and without 100 μ M 8-chlorophenylthio-cGMP (8-CPT-cGMP) for 15 min. The activation of ERK was assessed by immunoblotting for phospho-ERK (top), whereas the activation of c-Jun N-terminal kinase (JNK) was determined by the phosphorylation of GST-c-Jun protein in the JNK immunoprecipitated complex (bottom). Total ERK was determined using nonselective antibodies for phospho- and dephospho-ERK (middle). Note that ERK 1/2 and JNK activities are significantly increased in PKG-expressing cells and that 8-CPT-cGMP increases ERK and JNK activation.

PKG activation (Hassid *et al.*, 1994; Sciorati *et al.*, 1997) might well be explained by increased ERK activation and *c-fos* expression in contractile VSMC. Only in the synthetic phenotype expressing low levels of PKG would high concentrations of NO and cGMP inhibit ERK through cross-activation of PKA and phosphorylation of Raf-1 on serine-43. This is clearly a controversial area; but the point to be made is that it is critical to include those important controls that would address the issues of overlapping substrate specificity of kinases and the lack of specificity for activators and inhibitors of the kinases.

Summary and Perspectives

In this chapter we have attempted to achieve two goals: first, to give a synopsis of the role of the NO-cGMP signaling pathway in vascular smooth muscle function, with particular emphasis on the role of PKG, and second, to attempt to highlight some of the pitfalls and controversies surrounding much of the research in this actively growing area. As suggested in the introduction, the cGMP-PKG field is a relatively old one, and there has been much information published concerning the biochemistry and molecular biology of the pathway in general. A knowledge of the key issues surrounding PKG function in cells in order to more precisely interpret the results of the more current literature is important and was a goal of this chapter. With the role of NO assuming greater medical importance, newer studies concerning the role of cGMP-PKG signal transduction pathways are being added to the body of knowledge almost daily. These newer studies need to be interpreted carefully in light of not only the difficulties with using inhibitors and activators of the pathway, but also the cross talk observed with cyclic

nucleotide-dependent protein kinase pathways and the ease with which cyclic nucleotide-dependent protein kinases can catalyze phosphorylation of each other's substrates. Our only regret is that we could not cover more of the emerging roles of this fascinating signal transduction system. Such roles as the regulation of renin secretion (Gambaryan *et al.*, 1998), apoptosis (Pollman *et al.*, 1996), and brain function (Arancio *et al.*, 1995) by PKG are likely to be significant areas for basic and clinical research in the coming years.

With these concepts in mind, it is clear that the cGMP-PKG signal transduction pathway will assume major importance for understanding vascular function in physiological and pathophysiological settings. Drug development will almost surely be targeted toward regulating this pathway, as the ground has already been successfully broken with the appearance of sildenafil (Viagra) on the scene (Boolell *et al.*, 1996). Not to diminish in any way the positive impact this drug has had on the quality of human life, perhaps even more important pharmacological agents aimed at regulating the NO pathway, natriuretic peptide pathways, and the intracellular cGMP-PKG pathway in vascular disorders will be seen in the future.

NITRIC OXIDE (NO) FUNCTIONS AS A NEUROTRANSMITTER AND NEUROMODULATOR IN THE CENTRAL AND PERIPHERAL NERVOUS SYSTEMS. THE EFFECTS OF NO ON BLOOD VESSEL TONE AND NEURONAL FUNCTION FORM THE BASIS FOR AN IMPORTANT ROLE OF NO ON NEUROENDOCRINE FUNCTION AND BEHAVIOR. NO MEDIATES HYPOTHALAMIC PORTAL BLOOD FLOW, AND THUS AFFECTS NEUROPEPTIDE SECRETION, AS WELL AS MEDIATES NEUROENDOCRINE FUNCTION IN THE HYPOTHALAMUS–PITUITARY–ADRENAL AND THE HYPOTHALAMUS–PITUITARY–GONADAL AXES. NO INFLUENCES SEVERAL MOTIVATED BEHAVIORS INCLUDING SEXUAL, AGGRESSIVE, AND INGESTIVE BEHAVIORS. LEARNING AND MEMORY FUNCTIONS ARE ALSO INFLUENCED BY NO. TAKEN TOGETHER, NO IS EMERGING AS AN IMPORTANT CHEMICAL MEDIATOR OF NEUROENDOCRINE FUNCTION AND BEHAVIOR.

Introduction

As described in earlier chapters, the first biological function of nitric oxide (NO) was discovered in the circulatory system. Subsequently, NO was discovered to play a role in neuronal processes and in immune responses. In general, NO used in these three different roles is produced by three different isoforms of the nitric oxide synthase (NOS) enzyme. NO produced by endothelial NOS (eNOS) causes vasodilation and an increase in blood flow, whereas NO produced by inducible NOS (iNOS) helps macrophages to fight a pathogen. In the brain and other parts of the nervous system, NO derived from neuronal NOS (nNOS) activates signaling pathways and, in many ways, acts as a traditional neurotransmitter. As a signaling molecule, though, NO also has unique properties that are outlined later. NO derived from eNOS and

nNOS are both important in regulating several neuroendocrine and behavioral functions.

NO acts on neuroendocrine and behavioral processes generally in one of three ways: (1) indirectly, as NO derived from eNOS mediates blood flow, and differential blood flow can affect neuroendocrine secretion rates; (2) directly, as NO derived from nNOS affects neuronal functioning within the brain; and (3) hormonally, as NO derived from nNOS in endocrine glands or reproductive organs can regulate hormone release. In neuronal processes, glutamate is a common, but not the only, activator of NO release. Because elevated calcium, acting in conjunction with calmodulin, activates nNOS, normal presynaptic activity can cause NO release. As a signaling molecule, NO is unusual as it is a labile molecule at body temperature capable of easily crossing cell membranes. NO does not require a traditional postsynaptic

membrane-bound receptor. For NO to have a biological effect, however, a response cell must contain a “receptor.” The most common target of NO is the soluble guanylate cyclase (sGC) that, once activated, produces the second messenger, cGMP. cGMP can alter the excitability of a neuron by either directly acting on an ion channel, activating a cGMP-dependent protein kinase (PKG) that then can phosphorylate ion channels, or activating a phosphodiesterase that can alter cAMP levels. Depending on the target cell, NO can either increase or decrease the excitability of the target cell. NO was first shown to act as an anterograde messenger in the sea slug *Aplysia*, but it is also capable of acting as a retrograde messenger. Work on the pond snail *Lymnaea* has shown that a presynaptic neuron releasing NO can cause depolarizing potentials in a “follower” neuron at distances up to 50 μm , indicating that some NO-releasing and NO-responding cells can be separated by much larger distances than traditional pre- and postsynaptic cells.

The use of pharmacological agents that block synthesis of NO has been important in establishing a role for NO in neuroendocrine and behavioral pathways. A number of studies on the biological actions of NO have involved the use of nonspecific inhibitors of NOS, such as *N*-nitro-L-arginine methyl ester (L-NAME), *N*^G-monomethyl-L-arginine (NMMA), or *N*^G-nitro-L-arginine (L-NNA). A major drawback of these studies is that it remains unclear whether a certain outcome results from the inhibition of nNOS, eNOS, iNOS or a combination of these enzymes, or from alterations in other nonspecific, nitrogen-dependent processes. Specific inhibitors of NOS have been developed, such as 7-nitroindazole (7-NI), that more specifically inhibit nNOS than eNOS. 7-NI also has its limitations because more recent work suggests it can affect dopamine signaling. For any work examining the role of NO in biological pathways, converging evidence using different research approaches will be required. In this chapter, we describe how the use of pharmacological agents that block synthesis of NO, the use of knockout mice that lack one of the various isoforms of NOS, and neuroanatomical studies have revealed that NO appears to play an important role in the control of several neuroendocrine pathways and behaviors.

NO and Neuroendocrine Function

Hypothalamic–Pituitary–Adrenal Axis

The stress response in vertebrates involves the secretion of a group of steroids, the glucocorticoids (e.g., cortisol, in humans), from the cortex of the adrenal gland that act both to increase the mobilization of energy and to suppress nonessential functions, such as reproduction, growth, digestion, and the immune system. The release of glucocorticoids is controlled by the brain, and NO appears to play an important role in activating the hypothalamic–pituitary–adrenal (HPA) axis. A wide range of stressors can activate the HPA axis, and these include a lack of food (starvation), an immediate

threat of attack, and the immune system (specifically, high levels of cytokines). Regardless of the stressor, a common feature of the activation of the HPA axis is the release within the hypothalamus of the peptide corticotropin-releasing factor (CRF), which then activates cells in the anterior pituitary to release adrenocorticotrophic hormone (ACTH) into the circulatory system. ACTH acts on the adrenal glands to trigger the release of glucocorticoids.

NO release is linked to the activation of the HPA axis and CRF release because NO donors injected into the brain trigger the release of CRF from the hypothalamus. Although, the specific neural pathways by which stressors, such as starvation or the threat of attack, activate CRF release is not known, some of the signaling molecules that alter CRF release are known. These activators of CRF release include the catecholamines, prostaglandins, and neuropeptides. Two neuropeptides, oxytocin and vasopressin, both activate CRF release when injected centrally into the brains of rodents. The actions of both neuropeptides are suppressed by treatment with the inhibitor of NO production L-NAME, suggesting that both of these peptides depend on NO release to trigger CRF release. The most likely targets of oxytocin and vasopressin are CRF-containing cells in the paraventricular nucleus (PVN) of the hypothalamus.

Other activators of CRF include morphine and norepinephrine (NE). Morphine triggers the release both of NO within the median eminence of the hypothalamus and the release of CRF. This release of CRF is NO-dependent, providing another link between NO release and CRF release. Interestingly, the neurotransmitter NE triggers CRF release, but this is not dependent on NO release.

As mentioned, cytokines, including interleukin-1 (IL-1), IL-1 β , IL-2, and IL-2 β , can trigger the release of CRF from the central nervous system (CNS). The specific pathways by which the interleukins activate CRF release is not known. In the case of IL-1 β and IL-2, however, the triggering of CRF release is attenuated by NOS inhibitors, such as NMMA, suggesting the activation of CRF release by these cytokines is NO dependent. It is possible that cytokine actions on CRF release involve the indirect action of NO. For example, some cytokines may trigger increases in NO that then activate the release of NE, prostaglandins, acetylcholine, or neurohormones that in turn elicit the release of CRF. IL-2 and acetylcholine both trigger CRF release from hypothalamus, and both actions are inhibited by NOS inhibitors. Furthermore, it is possible that IL-2 actions are dependent on acetylcholine release.

Neuronal NOS is localized in discrete areas of the brain, including the PVN and supraoptic (SON) nuclei of the hypothalamus, both of which represent the major source of neurons containing CRF. Anatomically, then, NO production and CRF appear to be closely adjoined, but future work will be required to determine the multiple ways that NO release may be linked to CRF release. Taken together, it appears that multiple pathways exist for activating the release of CRF, some of which are NO dependent and some of which are not. A summary of some of the NO-dependent and NO-

independent pathways by which CRF is released is shown in Fig. 1.

Another mechanism for controlling NO and subsequent CRF release could involve the up- or downregulation of the nNOS protein. Within the hypothalamus, IL-1 β and CRF, itself, appear to trigger increases in nNOS mRNA. The functional significance of these changes are not known. Much of the research presented in this chapter indicates that NO often plays an excitatory role in causing the release of a signaling molecule. Interestingly, in the adrenal gland, where the glucocorticoids are made and released, nNOS expression is upregulated by high levels of stress. Additionally, in the adrenal gland NO acts to inhibit glucocorticoid release. The ability to increase levels of nNOS in the adrenal gland under stressful conditions in conjunction with NO acting as an inhibitor of glucocorticoid release in the adrenal glands may have developed as a useful mechanism for regulating the activity of the HPA axis.

Hypothalamic–Pituitary–Gonadal Axis

Neuroendocrine regulation of reproduction in vertebrates is complex and includes the control by the brain of the synthesis and release of sex steroid hormones from the reproductive organs. Of course, the sex steroid hormones themselves act on targets throughout the body, including the brain. At the center of this control over reproduction in males and females is the release of the peptide hormone gonadotropin-releasing hormone (GnRH) from the hypothalamus. NO appears to play an important role in regulating GnRH release. In mammalian species, GnRH neurons are widely distributed and form a loose continuum from the telencephalic diagonal band of Broca, and more dorsal septal areas, to the bed nucleus of the stria terminalis, and diencephalic areas (including subregions of the hypothalamus). GnRH neurons send axonal projections primarily to the median eminence to regulate anterior pituitary secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH), collectively known as the gonadotropins. In turn, the gonadotropins act on the gonads to regulate steroidogenesis and gametogenesis (LH and FSH, respectively). The activation of the hypothalamic–pituitary–gonadal (HPG) axis enables an animal to reproduce sexually. For GnRH to achieve its maximal effect on the release of LH and FSH, it must be released in a pulsatile manner.

Substantial evidence indicates that the release of GnRH is activated and modulated by the upstream release of NO. Because the release of GnRH is at the center of the control of reproduction, the control of the release of GnRH is the primary mechanism for activating or inhibiting reproduction. Anatomically, nNOS does not colocalize with GnRH neurons, but neurons with nNOS are found to closely adjoin GnRH cells in the hypothalamus and the median eminence. It is not clear whether NO directly acts on GnRH cells, but some evidence suggests that this is a possible pathway. The most common, but not the only, target of NO is the sGC that once activated triggers the production of cGMP. cGMP can

Figure 1 Schematic representation of how NO interacts with the HPA axis. Oxytocin (OXY), vasopressin (AVP), interleukin-1 β (IL-1 β), and IL-2 all can trigger the release of corticotropin-releasing factor (CRF), but this action is impaired by NOS inhibitors. Norepinephrine (NE) triggers CRF release, but this action is not disrupted by NOS inhibitors. Once released, CRF triggers the release of adrenocorticotrophic hormone (ACTH) from the anterior pituitary into the blood, and ACTH stimulates the release of the glucocorticoids (or stress hormones) from the adrenal glands.

then alter cell excitability and neurosecretion by acting through a variety of pathways. sGC was identified in the terminals of GnRH cells in the median eminence, suggesting that NO can directly act on GnRH cells. Additionally, NO application to the median eminence activates a sGC that triggers the release of GnRH. It remains possible that the actions of NO on GnRH cells can be indirect, and these possibilities will need to be explored with future research. Interestingly, immortalized GnRH cells show both nNOS mRNA and the ability to release GnRH when stimulated by NO. The cells also show increasing levels of secretory activity with increasing levels of cGMP, suggesting the use of the NO-activated sGC signaling pathway.

A number of signaling pathways activate NO release and directly, or indirectly trigger GnRH release. Both *in vivo* and *in vitro*, glutamate administration elevates GnRH and LH concentrations. Glutamate often acts on the NMDA receptor (which activates NOS through the influx of Ca²⁺), and glutamate may act on this subtype of glutamate receptor to reg-

ulate GnRH and gonadotropin secretion. Intracerebroventricular (icv) injections of NMDA lead to increased LH secretion in gonadectomized male and female rats, and NMDA receptor antagonists lead to reductions in GnRH and LH levels. Glutamate may also act through an alternate route to trigger GnRH release. Both glutamate and oxytocin activate the release of NE from the medial basal hypothalamus (MBH), and NE then appears to act on α_1 -adrenergic receptors to trigger the release of NO and GnRH. Incubation of hypothalamic explants with NE increases NOS activity; this increased NOS activity is blocked by the addition of prazosine, an α_1 -adrenergic receptor antagonist. Likewise, the actions of oxytocin and glutamic acid are blocked by phentolamine, a different inhibitor of the α_1 -adrenergic receptor, indicating that the actions of oxytocin and glutamic acid can be indirect. In contrast, NO donors such as sodium nitroprusside (SNP) activate GnRH release in a dose-dependent manner, and this action is not blocked by phentolamine, indicating that NO release is downstream of NE release. Morphine, anandamide, and leptin are other signaling molecules that can trigger increases in NO and GnRH release in the median eminence. For anandamide and morphine, these actions are inhibited by NOS inhibitors, suggesting that in these cases the induction of GnRH release is dependent on NO release.

Cytokines can both inhibit and activate GnRH release. Evidence indicates that IL-2 increases acetylcholine secretion, which triggers NO and GnRH release. Granulocyte macrophage colony-stimulating factor (GM-CSF) and IL-1 inhibit GnRH release. Interestingly, GM-CSF blocks the ability of NO to trigger the release of GnRH. This block likely results from the GM-CSF activating the release of the signaling molecule γ -aminobutyric acid (GABA). The actions of GABA are complex. In some studies GABA has been found to inhibit GnRH cells directly and prevent their activation by NO, whereas other studies report that it stimulates GnRH release. Interestingly, NO can also stimulate the release of GABA; SNP increases GABA release in cortical neurons and MBH explants *in vitro*. Exactly how NO and GABA interact in controlling GnRH release will need to be clarified in future research. A summary of some of the pathways by which NO interacts with GnRH release is shown in Fig. 2.

The immediate targets of GnRH are the gonadotropes in the anterior pituitary that release LH and FSH. NO may also play a role in the activity of the gonadotropes. At proestrus in rodents, levels of nNOS mRNA increase in the gonadotropes, and this increase appears to be activated by GnRH because GnRH antagonists block this increase. It is possible, then, that the increases in nNOS protein cause an increase in NO release within the gonadotropes that triggers increased amounts of LH and FSH release.

In addition to the effects of NO on GnRH secretion, NO is also involved directly in ovulatory processes. Treatment with L-NAME inhibits ovulation in rats. Fertility is reduced in female mice lacking the gene encoding the neuronal isoform of NOS (nNOS^{-/-}). To test for physiological defects

Figure 2 Schematic representation of how NO interacts with the HPG axis. NE, morphine, anandamide, leptin, and glutamate all can trigger GnRH release, but this action is disrupted by NOS inhibitors. Additionally, glutamate and oxytocin can trigger NE release that then activates the release of GnRH through an NO-dependent pathway. Granulocyte macrophage colony-stimulating factor (GM-CSF) can prevent NO from stimulating GnRH release. Once released, GnRH triggers the release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the anterior pituitary. LH and FSH, released into the blood, trigger the production and release of androgens and estrogens from the reproductive glands.

that could account for reduced fertility, the rate of ovulation as determined by the number of rupture sites on the ovaries, as well as the number of oocytes recovered from the oviducts, was evaluated. Female wild-type (WT) and nNOS^{-/-} mice did not differ in these parameters after mating with a WT male. Female nNOS^{-/-} mice had fewer ovulation rupture sites than WT females after GnRH treatment. Despite equivalent numbers of ovulation rupture sites after a superovulating dose of pregnant mare serum gonadotropin, fewer oocytes were recovered from the oviducts of nNOS^{-/-} mice as compared to WT mice. Thus, nNOS^{-/-} female mice display normal ovulation during natural estrus or after estrus induction with GnRH injections, suggesting that the central mechanisms of ovulation are intact. However, ova capture by the fallopian tubes was impaired during superovulation. Taken together, these results indicate that nNOS contributes to female fertility. Female eNOS^{-/-} mice display normal estrous cycles and essentially normal ovulatory mechanisms.

Behavioral Effects of NO

Circadian Organization

Behavior is organized on a temporal basis. It is critical for animals to breed, eat, sleep, socialize, drink, and locomote at the appropriate time of day or year. Several studies, using pharmacological agents, have indicated that NO is an important mediator of mammalian biological rhythms. In mammals, synchronization (entrainment) of circadian rhythms to the environmental light–dark cycle is mediated by the transmission of photic information from retinal ganglion cells to the suprachiasmatic nuclei (SCN) of the hypothalamus, which functions as a self-sustained circadian clock. Glutamate is involved in this light transmission process, and it appears to act on NMDA receptors in the SCN. Glutamate binding can activate NOS. Several lines of evidence implicates NO in light transmission from the eye to the SCN. Administration of L-NAME blocks the effects of light on biological rhythms in locomotor activity or physiological processes in the SCN. L-NAME has many nonspecific effects on blood flow and pressure in the brain because it inhibits both eNOS and nNOS. Consequently, L-NAME also affects many other nitrogen-dependent physiological processes.

Despite the pharmacological evidence that NO is crucial in mediating circadian rhythms, work with transgenic mice suggests otherwise. Both nNOS $-/-$ and eNOS $-/-$ mice show normal entrainment to daily light–dark cycles, and they showed normal phase shifts of locomotor activity in response to light pulses. Further research is necessary to clarify the contribution of NO to circadian organization of behavior and physiology.

One study suggests that NO plays some role in the temporal organization of behavior. Neuronal NOS $-/-$ mice have no obvious defects in locomotor activity, breeding, long-term depression in the cerebellum, long-term potentiation in the hippocampus, or overall sensorimotor function. Because the cerebellum possesses the greatest numbers of nNOS neurons in the brain, it was surprising that presumed cerebellar functions such as balance and coordination were generally normal in nNOS $-/-$ mice. However, this conclusion was based on studies that were conducted during the day (between 1400 and 1600 hours, lights on at 0700 hours) when the animals are typically inactive. When the animals were tested during their nocturnal, active period, dramatic abnormalities in balance and motor coordination were evident in nNOS $-/-$ mice.

Reproductive Behaviors

NO affects reproductive behavior. There have been reports that both sexual motivation and performance are influenced by NO, though much of the effects of NO on male sexual performance reflect the direct consequences of the well-established effects of NO on penile erectile function. Generally, sexual motivation in male rats is not affected by

manipulations of NO levels. Treatment of male rats with NOS inhibitors (i.e., L-NAME) did not reduce the latency to first mount or the number of mounting attempts of estrous females by male rats. Male nNOS $-/-$ mice displayed normal sexual motivation to mount with estrous females; however, male nNOS $-/-$ mice exhibited inappropriate persistent mounting attempts of anestrous females.

Administration (intraperitoneal) of L-arginine, the natural substrate for NOS, increased the percentage of naive male rats copulating and improved sexual performance in sexually experienced males. These behavioral effects were reversed in rats receiving systemic injections of L-NAME. Administration (icv) of L-arginine did not affect reproductive behavior. L-NAME icv infusion prevented ejaculation of naive rats (100 μ g/rat), but did not affect ejaculation of experienced male rats at doses up to 300 μ g/rat. Systemic treatment of sexually naive male rats with 30 or 60 mg/kg of L-NAME reduced the number of ejaculations by 43 and 86%, respectively. In both experimental groups, the number of intromissions was reduced, although mounting behaviors were elevated; increased number of mounts is common with penile erectile dysfunction in rats. The number of ultrasonic vocalizations increased; these vocalizations are an important component of sexual behavior in rats. Systemic L-NAME administration impaired copulation, reduced the number of *ex copula* penile erections, increased the number of *ex copula* seminal emissions, and decreased the latency of first seminal emission of male rats. Treatment with L-arginine increased the number of penile reflexes but had no other effects on male rat reproductive behavior. There is no obvious explanation for the conflicting reports on the behavioral effects of L-arginine treatment in rats. Male mice with targeted deletion of the gene encoding nNOS exhibited equivalent penile intromissions and ejaculations as WT males when paired with estrous females. This outcome was surprising because it had been firmly established using L-NAME and other NOS inhibitors that NO mediated penile erectile function. However, it appears that eNOS is upregulated in nNOS $-/-$ animals, and that eNOS, not nNOS, mediates penile erections.

NO functions in the brain to affect sexual behavior. Expression of nNOS mRNA in the PVN of the hypothalamus was nearly doubled in sexually potent male rats as compared to impotent males. Reproductive performance in male golden hamsters (*Mesocricetus auratus*) is dependent on chemosensory and endocrine stimuli processed in limbic neural circuits. Neurons expressing nNOS in hamster brains were discovered in the medial amygdala nucleus (Me), the bed nucleus of the stria terminalis (BNST), and the medial preoptic area (MPOA). nNOS-positive fibers were observed in the stria terminalis and the ventral amygdalo–fugal pathway; this pathway connects the Me with the BNST and MPOA. Several of the NOS-positive neurons in the ME and the medial preoptic nucleus (MPN) also contained androgen receptors. Castration decreased the number of NOS-positive neurons in the MPN, suggesting that NOS may be regulated by gonadal steroids.

The involvement of NO in male reproductive behavior appears to be conserved throughout vertebrate evolution. NO plays an important role during courtship of urodele crested newts (*Triturus cristatus*). Courtship is complex in this species with four distinct stages of courtship. Females that are receptive remain relatively immobile and close to the male during his approach, fanning, lashing, and spermatophore deposition, whereas nonreceptive females move away from courting males. Some males do not court in the presence of receptive females. Brain NOS was measured in receptive and nonreceptive females, in males at various points during courtship, and in noncourting males. Mating success of male newts was characterized by high brain NOS activity that progressively increases during each of the courtship phases and returned to baseline levels after spermatophore deposition. Inactive males exhibited the lowest brain NOS activity. There was no difference among female newts regardless of their receptive state. Thus, NO appears important in male, but not female, newt reproductive behavior.

NO appears to mediate female sexual behavior in rats. Receptive behavior can be elicited in estrogen-primed, ovariectomized rats with progesterone treatment. Receptive behavior is usually indicated by the display of the mating posture, lordosis, in response to male mounting behavior. When N^G -monomethyl-L-arginine was microinjected icv into the third cerebral ventricle of awake and freely moving female rats, lordosis was not observed after progesterone administration. Microinjections (icv) of N^G -monomethyl-D-arginine, a compound that does not inhibit NO production, did not inhibit lordosis after progesterone administration. Microinjections (icv) of SNP, a substance that spontaneously releases NO, promoted the display of lordosis of estrogen-primed rats in the absence of progesterone. Lordosis that was evoked in estrogen-primed female rats by either progesterone or SNP could be blocked by microinjections (icv) of GnRH antiserum. Thus, it appears that progesterone normally causes the release of NO that stimulates GnRH secretion from the hypothalamus, which facilitates lordosis in rats.

In contrast, mating behavior appeared normal in nNOS $^{-/-}$ female mice, though fertility rates are lower than for WT mice. nNOS $^{-/-}$ females did not differ from WT females in the latency to first lordosis posture or in the number of lordosis postures during a 30-min mating test. If impregnated, then nNOS $^{-/-}$ and WT females had equivalent litter sizes at birth and at weaning, and their litters displayed normal sex ratios. As noted above, NO appears to be involved in the mechanisms of ovulation, and the reduction of fertility among nNOS $^{-/-}$ females might reflect this physiological defect.

Aggressive Behaviors

There are no published reports that L-NAME or other nonspecific NOS inhibitors affect aggression. However, nNOS $^{-/-}$ males are dramatically more aggressive and sexually persistent than WT mice. When examined in an

intruder-resident test of aggression, these nNOS $^{-/-}$ mice engaged in three to four times more aggressive encounters than WT mice. Nearly 90% of the aggressive encounters were initiated by the nNOS $^{-/-}$ animals. Similar results were obtained in dyadic or group encounters in neutral arenas. In all test situations, male nNOS $^{-/-}$ mice rarely displayed submissive behaviors.

Behavioral studies of mice with targeted deletion of specific genes suffer from the criticism that the gene product is not only missing during the testing period, but missing throughout development when critical ontogenetic processes, including activation of compensatory mechanisms, may be affected. To address this criticism, mice were treated with 7-NI, a specific inhibitor of nNOS formation *in vivo*. Mice treated with 7-NI displayed substantially increased aggression in two different tests of aggressiveness as compared to control animals. Drug treatment did not affect non-specific locomotor activities. Importantly, NOS activity in brain homogenates was reduced >90% in 7-NI-treated mice. Similarly, immunohistochemical staining for citrulline revealed a dramatic reduction in 7-NI-treated animals. Taken together, 7-NI inhibited NOS staining in the limbic system and reduced citrulline immunohistochemical staining, suggesting that NO formation was virtually eliminated in these experimental animals. Because 7-NI treatment in WT mice caused aggression to be elevated to the levels displayed by nNOS $^{-/-}$ mice, it appears that nNOS is an important mediator of aggression.

Plasma androgen concentrations can affect the display of aggressive behavior. There were no differences between nNOS $^{-/-}$ and WT mice in blood testosterone concentrations either before or after agonistic encounters. However, more recent data on castrated nNOS $^{-/-}$ males suggest that testosterone is necessary, but not sufficient to promote increased aggression. Castrated nNOS $^{-/-}$ mice displayed low levels of aggression that were equivalent to the aggression observed among castrated WT males. Androgen-replacement therapy restored the elevated levels of aggression in nNOS $^{-/-}$ mice. Importantly, inappropriate aggressiveness was never observed among female nNOS $^{-/-}$ mice; however, aggressive behavior was not examined in female nNOS $^{-/-}$ mice in the context of maternal aggression, during which WT females are highly aggressive toward an intruder. There were no sensorimotor deficits among the mutant mice to account for the increased aggression.

It is interesting to note that males lacking the gene encoding the endothelial isoform of NOS are virtually never aggressive. Although eNOS was initially reported to be localized in neural tissue, work using *in situ* hybridization failed to locate eNOS in neurons; eNOS is found only in moderate to large blood vessels in the brain. Why these mice are so docile is not known. Blood concentrations of testosterone are normal. eNOS $^{-/-}$ males have elevated blood pressure, but these mice remain very docile even when the hypertension is treated. Perhaps NO from endothelial sources in the brain relax the blood vessels and allow more blood flow and, subsequently, more neuroendocrine products

to be delivered. A summary of the reproductive and aggressive behaviors of the nNOS^{-/-} and eNOS^{-/-} mice is shown in Fig. 3.

Female mice typically only display aggression when defending a nest of newborn pups. The onset of maternal aggressive behavior is dependent on the hormones released during pregnancy and lactation, whereas maintenance of maternal aggression depends on sensory feedback from the nursing pups. Using antibodies to citrulline, an indirect indicator of NO, it was determined that a small group of neurons in the hypothalamus was involved in the regulation of maternal aggression. Furthermore, nNOS^{-/-} mothers showed normal maternal care, but no maternal aggression in response to a male intruder. Mothers missing the gene encoding eNOS display normal maternal aggression. These results suggest that female mice release NO from neurons within specific regions of the hypothalamus to trigger maternal aggression. These results also indicate that males and females use fundamentally different mechanisms to regulate aggression.

Regulation of Feeding

As with many behaviors, feeding behavior can be triggered by a number of stimuli. For example, the sight and smell of food, hunger, and even the time of day can all help to trigger feeding behavior. Feeding behavior itself is complex and includes sniffing, chewing, swallowing, and digesting. The neural pathways underlying feeding are largely unknown, but it is likely that the stimulation of olfactory and

visual pathways helps to activate the neural circuitry underlying this behavior. A range of evidence suggests that NO, acting as a neuromodulator, is released in the brain during feeding behavior.

NOS blockers consistently decrease feeding in mice, rats, and chickens, suggesting that NO is used to activate feeding behavior. For example, in food-deprived rats and mice, the NOS inhibitor L-NNA decreases food intake even though the animals should be highly motivated to eat. This response, however, can be reversed by L-arginine, suggesting that feeding can be reinitiated by the production of NO. Additional evidence that NO activates feeding comes from research on “fat” rats and mice. In the obese rats, the NOS inhibitor L-NAME decreases feeding. As one might expect, the obese mice exhibit increased levels of nNOS in the brain relative to WT, indicating that the obesity may result from the overproduction of NO and overstimulation of the feeding circuits.

NO may activate feeding behavior, but the site of its actions within the feeding neural circuit is unknown. Central NE administration increases food intake in rats, and this increase is reduced by coadministration of α_2 -receptor antagonists, suggesting that NE acts on α_2 -receptors to modulate feeding. In chickens, a specific α_2 -agonist, clonidine, increases food intake, but coadministration of L-NNA attenuates this increased food intake in a dose-dependent manner, indicating that NO release may be downstream of NE action. NOS has been localized to areas known to be involved in the control of feeding, particularly in the PVN of the hypothalamus. Food deprivation studies have documented a decrease in the levels of nNOS in the PVN and SON of the hypothal-

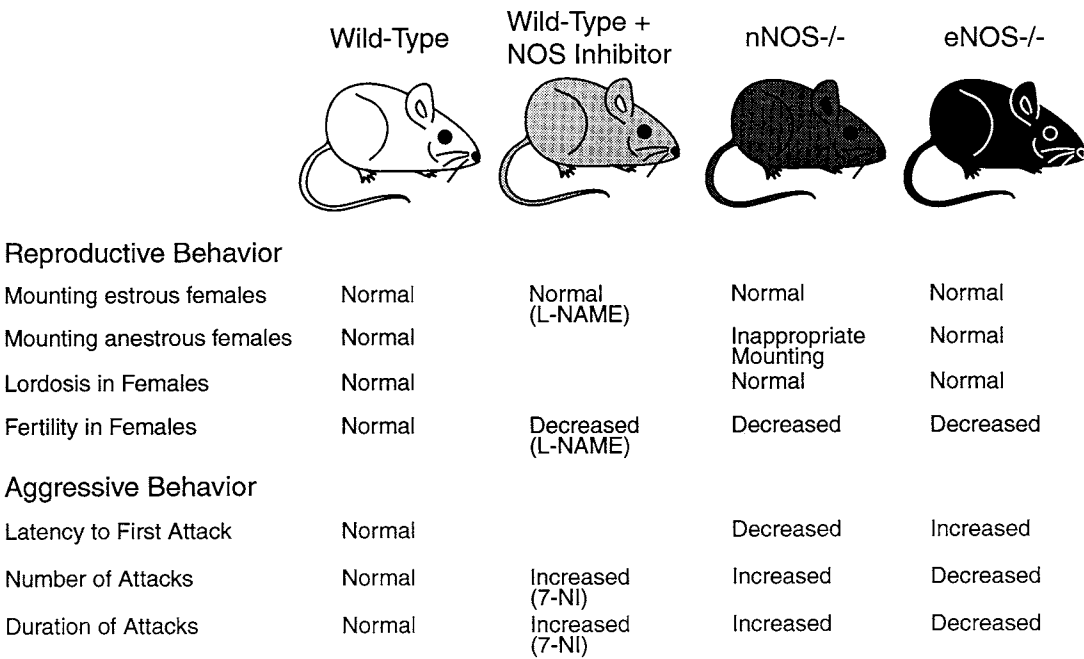

Figure 3 Summary of reproductive and aggressive phenotypes of wild-type mice, wild-type mice exposed to pharmacological inhibitors of NOS, and knockout mice lacking nNOS and eNOS. The aggressive behavior is specific to male mice only. The use of the specific nNOS inhibitor 7-NI produced a behavioral phenotype that matches the nNOS^{-/-} mice but not the eNOS^{-/-} mice.

amus of rats. The PVN (and also the SON) play a role in reproductive behaviors, and consequently, it is possible that decreases in nNOS and NO production in these nuclei help to shut down reproductive behaviors in times of low food. Interestingly, nNOS levels are increased in the PVN and SON during water deprivation, indicating that NO release may be involved in drinking behavior.

The relative amount of food intake decreases as animals, including humans, age. One possibility for this observation is that diminished production of NO accounts for decreased food intake during aging. In mice, the NOS inhibitor L-NAME shows greater efficacy in reducing feeding in older animals, indicating that mice may rely increasingly on NO to activate feeding as they age. Whether decreases in food intake during aging in rodents, or humans, results from changes in the production or use of NO remains to be determined.

As with the activation of any neural circuit underlying a behavior, the release of a given neurotransmitter, or neuromodulator, such as NO, not only results from the release of an upstream signaling molecule, but also triggers the release of a downstream signaling molecule. Which cells trigger NO release, which cells release NO, and which cells respond to NO in feeding behavior remain unspecified. The peptide hormone leptin is involved in controlling body weight of rodents, and increased leptin concentrations result in decreased food intake. Interestingly, central injection of leptin causes a decrease in NO production, and it is possible that leptin reduces feeding by inhibiting NO release. The neuromodulator serotonin (5-HT) may also play a role in controlling feeding, but whether or how serotonin and NO interact remains to be determined. Food deprivation leads to a reduction in brain 5-HT levels in rats. L-NNA reduces food intake in food-deprived animals but increases 5-HT levels in the diencephalon of rats. This inverse relationship between 5-HT and NOS levels suggests that NO may regulate feeding through a 5-HT mechanism.

Invertebrate Feeding Behavior

In the pond snail *Lymnaea stagnalis*, feeding behavior is simpler than that in vertebrates and involves a stereotyped pattern of muscle contractions that is driven by a stereotyped firing activity of motoneurons in the CNS. The production of snail feeding behavior is extremely sensitive to sensory input, and application of sugar water to the lips alone will activate the feeding behavior. An advantage of studying invertebrate behaviors is that the CNS can be isolated from the body and still can produce a behavioral motor output. In the case of *Lymnaea*, the lips and the CNS (still attached to one another) can be isolated, and application of sugar water to the lips activates a fictive feeding behavior from the CNS. As in vertebrates, NO plays a role in activating the feeding circuit. The sensory cells in the snail lips contain high levels of NOS, and application of an NO donor activates feeding behavior, even in the absence of sugar water. Likewise, use of hemoglobin, an NO scavenger, disrupts the ability of sugar

water applied to the lips to activate the feeding motor output, indicating that NO is normally released to trigger feeding.

As mentioned, feeding behavior in *Lymnaea* involves a stereotyped output of motoneuron firing. This pattern of firing is driven by a central pattern generator, and within the CNS the electrical stimulation of individual modulatory interneurons can also trigger the stereotyped fictive feeding behavior. Interestingly, NO release only appears to be involved in the activation of modulatory interneurons by sensory neurons because NO scavengers inhibit the ability of sucrose to stimulate these interneurons and the behavior, but they do not disrupt the ability of the modulatory interneurons to trigger the behavior. Consequently, the release of NO by sensory neurons as a result of sugar water activation is the first step and possibly the only role NO release plays in activating snail feeding. Among vertebrates, whether NO acts only at one level and where in the pathway NO release occurs in stimulating feeding remain unknown. An additional complication of feeding in both vertebrates and invertebrates is whether NO plays a role in activating movement and locomotory behaviors involved in the searching for food.

Learning and Memory

Inhibition of NOS impairs spatial learning in mice and rats. It appears that NO is important during initial acquisition, but according to many researchers the role of NO on the mechanisms of spatial learning remains unspecified. NOS inhibitors might affect learning by affecting blood pressure or other nitrogen-dependent processes. NOS inhibition has also been reported to impair social and olfactory memory as well as performance in some inhibitory avoidance learning paradigms in rats. Other laboratories have reported no effect of NOS inhibition on passive avoidance. Inhibition of NOS does not impair visual or spatial discrimination, nor does it affect sensorimotor or motivational processes. Sensorimotor skills are not impaired in nNOS^{-/-} mice.

The role of NO in learning and memory appears to have been conserved throughout the animal kingdom. NOS inhibition has been reported to impair learning and memory processes in honeybees (*Apis mellifera*), crickets (*Pteronemobius* spp), octopuses (*Octopus vulgaris*), and goldfish (*Carassius auratus*).

Many reports suggest that NO is part of the mechanism underlying learning and memory. Long-term potentiation (LTP) and long-term depression (LTD) are stable and enduring increases or decreases, respectively, in the magnitude of neuronal responses after afferent cells to the region have been stimulated with bursts of electrical stimulation of relatively high or low frequency, respectively. Because afferent neural activity affects firing patterns, the existence of retrograde messengers has been proposed. NO is a candidate molecule to serve as the retrograde messenger in LTP and LTD, although there have been conflicting reports about the role of NO in the mediation of LTP and LTD.

Again, LTP and LTD are forms of synaptic plasticity that are thought to be involved with learning and memory. Calcium influx through postsynaptic NMDA receptor channels and enhancement of glutamate release by Schaeffer collaterals is thought to be required for induction of LTP in the CA1 region of hippocampal slices; further, it has been hypothesized that LTP requires release of a retrograde messenger from postsynaptic CA1 pyramidal cells. NO may act as a retrograde messenger because NO produces an increase in the frequency of spontaneous miniature excitatory postsynaptic potentials and observations that direct application of NO elicits LTP. The establishment of LTP is blocked by NOS inhibitors and hemoglobin that binds NO blocks LTP. Furthermore, NOS inhibitors directly injected into CA1 pyramidal neurons block LTP. Support for the contention that postsynaptically generated NO acts directly on the postsynaptic neuron to produce LTP is the observation that intracellular application of an NO scavenger or use of a UV-sensitive NO donor elicits LTP. Similar evidence exists for a role of NO in LTD. Genetic knockout of nNOS or eNOS failed to support the role of NO in LTP. LTP in nNOS null or eNOS null mice appeared normal and can still be blocked by NOS inhibition. Kandel and colleagues generated double knockout mice lacking both nNOS and eNOS expression and reported that hippocampal LTP in the stratum radiatum of CA1 was markedly reduced. These mutant mice showed normal LTP in the stratum oriens of hippocampal CA1. Thus, there is both NO-dependent and NO-independent LTP. LTP in wild-type mice may be mediated through eNOS as adenovirus-mediated disruption of eNOS activity in wild-type hippocampal slices eliminates NO-dependent LTP. Some studies suggest that NO might help regulate the threshold for LTP induction. An overview of the possible site of action of NO in mediating LTP in the hippocampus is shown in Fig. 4.

Other studies also support a role for NO in synaptic plasticity. Calcium-dependent activation of nNOS and NO generation via stimulation of the NMDA receptor in cultured cortical neurons activates the Ras–ERK (extracellular signal receptor kinase) pathway. NMDA-stimulated phosphorylation of the cyclic AMP-response element binding protein (CREB), a downstream effector of ERK, is also NO dependent. Activation of the Ras–ERK pathway by NO may be mediated by direct activation of Ras GTPase activity, presumably by nitrosylation of cysteine through a redox-sensitive interaction. Because calcium-dependent activation of the Ras–MAPK pathway is considered to be a major pathway of neural activity-dependent long-term changes in the nervous system, NO may be a key mediator linking activity to gene expression and long-term plasticity.

Conclusions

The release of NO plays an integral role in several neuroendocrine pathways and is a well-established mediator of a number of behaviors. Neuroendocrine pathways and be-

Figure 4 Schematic diagram of the hippocampus and the subregions where NO-dependent and NO-independent long-term potentiation (LTP) may occur. Information in the hippocampus typically flows from the dentate gyrus to the CA3 region and on to the CA1 region. LTP can be recorded from the CA1 region. In one subregion of the CA1, the stratum radiatum, LTP is impaired in mice lacking eNOS and nNOS, but in a second subregion, the stratum oriens, LTP is normal, suggesting that NO-dependent and NO-independent forms of LTP exist.

haviors are often associated with one another, and NO may play a role in maintaining this link. Because NO can regulate blood flow and act as a neuromodulator, it possesses two main mechanisms for controlling neurosecretion and behavior. Significant progress has been made in understanding how the release of NO is controlled, where NO is released, and how NO acts on its targets. With the advent of pharmacological inhibitors of specific isoforms of NOS as well as spatial and temporal gene activation and inactivation, it is likely that additional neuroendocrine and behavioral roles of NO will be discovered.

IN THIS CHAPTER, WE REVIEW THE ROLE OF NO IN REGULATION OF THE CEREBRAL CIRCULATION AND AS A MECHANISM OF BRAIN INJURY DURING EXPERIMENTAL STROKE AND CEREBRAL ISCHEMIA. IT IS CLEAR THAT THERE ARE A VARIETY OF NO-LINKED MECHANISMS THAT PROTECT VASCULAR FUNCTION DURING ISCHEMIA BUT THAT ALSO POSE A THREAT TO NEURONS, PARTICULARLY GLUTAMATERGIC NEURONS. PRO-OXIDANT MECHANISMS INVOLVING THE CHEMICAL INTERACTION OF NO AND SUPEROXIDE AND FORMATION OF PEROXYNITRITE LEAD TO MITOCHONDRIAL DYSFUNCTION AND DNA DAMAGE. SUCH PATHOLOGY ENTRAINS DOWNSTREAM MECHANISMS LINKED TO PARP ACTIVATION AND FURTHER ENERGY DEPLETION. THE ESSENTIAL PRINCIPLE TO BE GLEANED IS THAT THE OVERALL ROLE OF NO IN CEREBRAL ISCHEMIA IS DEPENDENT ON A DYNAMIC BALANCE BETWEEN THESE TWO STATES: DIRECT NEUROTOXICITY DUE TO NO OVERLOAD AND VASCULAR DEFECTS DUE TO NO DEFICIENCY. SIMILARLY, THE THERAPEUTIC VALUE OF INHIBITING NOS AND NO FORMATION DEPENDS ON OUR ABILITY TO MANIPULATE THIS BALANCE EFFECTIVELY.

Introduction

Cerebral ischemia is defined as a reduction in cerebral blood flow (CBF). Cerebral ischemia may occur as a result of a variety of different pathological mechanisms, and it may result in devastating neurological sequelae. Ischemia may be complete and global, in which case CBF ceases (e.g., cardiac arrest, severe increase in intracranial pressure); it may be incomplete and global, in which case CBF is reduced throughout the brain (e.g., severe hypotension, moderate increase in intracranial pressure); or it may be focal, in which case there is a gradient of CBF reduction, with the greatest reduction occurring in the core of the lesion and less reduction in regions more distant from the core (e.g., ischemic stroke). In this chapter we provide an overview of basic principles regarding the role of nitric oxide (NO) in control of baseline CBF and blood flow in important peri-ischemic states such as hypoglycemia and seizures; we also discuss the role that NO plays in the evolution of experimental stroke and ischemia as well as the evidence for the importance of

interrupting NO overproduction and downstream mechanisms of injury.

Because NO is highly reactive and difficult to measure, much of our understanding of this molecule in the cerebral circulation and in brain injury comes from the study of its synthetic enzyme family, the nitric oxide synthases (NOSs). At present, three distinct isoforms have been characterized; each one is the product of a different gene. All known isoforms utilize arginine and NADPH as substrates and produce NO as a coproduct with citrulline. The characterization of NOS was first accomplished in resting endothelium; therefore it was considered to be constitutive and labeled as eNOS (type III by later nomenclature). In activated macrophages and cells such as glia, NOS was found to be calcium independent and to be induced by combinations of cytokines; consequently, it was referred to as inducible NOS (iNOS or type II NOS). A third general category of NOSs, neuronal NOS (nNOS or type I), is particularly important in brain because of its abundance relative to other isoforms. Like eNOS, nNOS is calcium dependent and historically con-

sidered to be constitutive, although it is increasingly clear that this “constitutive” enzyme is actually subject to expressional control by transcript diversity and by several brain conditions, including cerebral ischemia. Consequently, nNOS is not static, and cell-type-specific transcription and splicing factors may increase or decrease its expression in naive or injured tissue (for review, see Boissel *et al.*, 1998).

All of the NOS isoforms have been implicated in the pathophysiology of cerebral ischemia and in regulation of CBF. In addition, accumulating evidence suggests diverse expression of NOS isoforms in tissue other than endothelial cells, neurons, glia, and inflammatory cells. For example, both iNOS and nNOS are expressed and functional in vascular smooth muscle under a variety of physiological and disease-related states (Gunnnett *et al.*, 1998; Papadaki *et al.*, 1998; Boulanger *et al.*, 1998; Meng *et al.*, 1998; Hecker *et al.*, 1999). Further, there can be crossover in expression of NOS isoforms within the normal brain, for example, expression of eNOS in hippocampal neurons (Dinerman *et al.*, 1994). Vascular behavior and ischemic outcomes in the intact animal must therefore be analyzed with these complexities in mind.

Last, much of our understanding of NO-mediated ischemic injury has been based on data with enzyme inhibitors of limited specificity among NOS isoforms. Specific eNOS inhibitors are not yet available as pharmacological probes, although the crystal structure of the enzyme has been resolved (Fischmann *et al.*, 1999). Selective nNOS inhibitors have been developed, but their utility, *in vivo*, has been limited by poor solubility in physiological solutions, poor blood–brain barrier permeability characteristics, and only moderate specificity for the nNOS isoform. When comparing results from different laboratories, it is important to have an accurate quantitation of the NOS inhibition that is produced by the particular pharmacological probe in each study. The activity of the enzyme is most frequently assessed by measuring labeled citrulline production in brain biopsy samples post mortem (Traystman *et al.*, 1995) or in *in vivo* microdialysates (Bhardwaj *et al.*, 1995, 1997a,b), or activity is assessed by a more indirect approach such as measuring a physiological response to an intervention known to be mediated through NO. One conclusion drawn from these numerous studies is that even in the presence of a standard dose of inhibitor, the resulting degree of NOS inhibition in brain is variable and depends on the route of administration and the species and strain under investigation (Traystman *et al.*, 1995). In addition, current techniques for confirming functional enzyme inhibition can only provide a measurement of whole-tissue NOS activity, that is, the combined activity of all isoforms without distinction among nNOS, eNOS, or iNOS.

NO and Basal Cerebral Blood Flow

Both cerebral endothelium and, less prominently, nitroindergic neural activity supply NO to vascular smooth muscle, activating soluble guanylyl cyclase. This results in conversion of guanosine triphosphate to 3',5'-cyclic guanosine

monophosphate (cGMP) and in vascular relaxation (Ignarro *et al.*, 1982, 1987). In addition to direct vasodilation, NO can inhibit vasoconstriction produced by other agonists (e.g., endothelin 1) (Chen *et al.*, 1999). Less well studied is nitroindergic vasodilation within brain. Cerebral arteries, including the anterior and middle cerebral arteries, caudal circle of Willis, and some pial vessels, are innervated by NOS-containing nerves that originate largely via the sphenopalatine ganglia (Nozaki *et al.*, 1993). Electrical stimulation of porcine cerebral vessels results in NO liberation and vessel relaxation (Toda and Okamura, 1992; Tanaka *et al.*, 1999).

In general, intravenous administration of a nonspecific NOS inhibitor decreases CBF (Greenberg *et al.*, 1994). Regions with poor blood–brain barrier function and with high NOS activity exhibit the largest reductions in CBF after administration of a nonspecific inhibitor. The decrease in CBF is not associated with a change in cerebral oxygen consumption; therefore, the mechanism is not related to a decrease in oxygen utilization (Greenberg *et al.*, 1994). As would be expected, CBF reduction in response to competitive inhibitors can be reversed by subsequent administration of substrate, namely, L-arginine. Brain surface pial arterioles dilate *in vivo* to topically applied L-arginine (which presumably increases NO generation) and constrict in response to topical nonspecific NOS inhibitors (Rosenblum *et al.*, 1990). In contrast, systemic administration of a fairly selective nNOS inhibitor has little effect on resting CBF (Harukuni *et al.*, 1999; Z. G. Zhang *et al.*, 1996), suggesting that neuronal NO is not important in regulating basal blood flow. In summary, vascularly derived NO appears to be an important mediator of resting cerebrovascular tone *in vivo*.

NO and Cerebrovascular Reactivity

NO has also been considered to be an important mediator of cerebrovasodilation resulting from hypercapnia, administration of inhaled anesthetics, hypoglycemia, and seizures. We will briefly provide the evidence in these states because each is important to understanding the importance of NO in mechanisms of cerebrovascular control, and each may coexist with experimental or clinical ischemia. We emphasize the evidence for a role of NO in CBF hyperemia resulting from inhalational anesthesia because many experimental data have been acquired in animals anesthetized with these agents. Therefore, if NO is to be proved as an important mechanism in ischemic pathophysiology, one must also consider the potential effects of NO produced by inhalational anesthetics on brain injury.

NO and Carbon Dioxide Reactivity

Cerebrovascular dilation in response to hypercapnia and constriction in response to hypocapnia are a universal finding in mammals. Toda *et al.* (1993) demonstrated that removal of endothelium in large cerebral blood vessels isolated from dog and monkey does not affect the cerebral vas-

cular response to hypercapnia (Toda *et al.*, 1993). These data suggested that NO derived from endothelium (or other endothelium-derived relaxation factors) are not important in the mechanism of cerebral vascular dilation during hypercapnia. However, because the level of PCO_2 (110–120 mmHg) was potentially high enough to cause nonspecific direct relaxation of vascular smooth muscle, it remains difficult to extrapolate these results to more physiologically relevant situations. Other investigators (Bertalanffy *et al.*, 1993) have found that *in situ* ablation of pial vessel endothelium with light at visible wavelengths did not affect pial arteriolar dilation to hypercapnia. Together these *in vitro* data (Toda *et al.*, 1993; Bertalanffy *et al.*, 1993) suggest that vascular endothelium is not important in hypercapnia-induced cerebral vasodilation in monkey, dog, or cat.

However, the role of NO in the mechanism of cerebrovasodilation to hypercapnia *in vivo* is controversial. In the cat, one group of investigators has reported a significant role of NO in mediation of regional blood flow during hypercapnia (arterial PCO_2 55–65 mmHg) in brain and spinal cord (Santor *et al.*, 1994). However, others have demonstrated that NOS inhibition does not alter hypercapnia-induced dilation when surface pial vessels are directly visualized. In another study, administration of nonspecific NOS inhibitors substantially reduced CBF hyperemia with hypercapnia in rat (Wang *et al.*, 1992). However, it is difficult to interpret these data given that NOS inhibition decreased baseline CBF and increased blood pressure, with the net result of increased baseline cerebrovascular resistance. Therefore, although the increase in CBF during hypercapnia was smaller after the NOS inhibitor as compared to before inhibitor administration, this result is not straightforward. Because baseline cerebrovascular resistance was high, the absolute reduction in cerebrovascular resistance during hypercapnia was not different from that observed prior to NOS inhibition. Thus, it could be concluded that the overall cerebrovascular response to hypercapnia is not affected by NOS inhibition. We have evaluated the effect of NOS inhibition on the cerebral vascular response to hypercapnia in isoflurane-anesthetized monkeys (McPherson *et al.*, 1995), carefully controlling blood pressure and brain temperature. During hypercapnia, arterial PCO_2 was increased from 40 to 50–70 mmHg. Despite confirmation of complete NOS inhibition in brain homogenates from these animals, we found little effect on vascular reactivity during hypercapnia in most brain vascular beds. In cortex, a modest 30% attenuation of the hypercapnic response was observed. In summary, NO is not a major mediator of cerebral vascular dilation in response to hypercapnia.

Role of NO in Cerebrovasodilation Produced by Inhalational Anesthetics

Inhalational anesthetics cause an increase in CBF *in vivo* and vasodilation of cerebral blood vessels *in vitro*. The cerebral hyperemic response to inhalational anesthetics is only transient in subprimate mammals (Brian *et al.*, 1990), but it

is sustained in primates (McPherson *et al.*, 1994). Many different mechanisms have been considered in these vascular actions, including alterations in cellular calcium homeostasis, excitatory amino acids, free radicals, and prostanoids. Whether NO mediates the hyperemia induced by inhalational anesthetics has been evaluated both *in vivo* and *in vitro*, and the resulting data are again based predominately on inhibitor studies. Exposure of middle cerebral artery rings (Flynn *et al.*, 1992) and basilar artery (Jensen *et al.*, 1992) to inhalational anesthetics produced a dose-dependent vasodilation that was not affected by inhibition of NOS or removal of endothelium. Inhalational anesthetics have also been demonstrated to attenuate vasodilator mechanisms that depend on NO production (Uggeri *et al.*, 1992). Although *in vitro* data suggest that neither endothelium, NO, nor cGMP play an important role in vasodilation from inhalational anesthetics, *in vivo* experiments support a role for NO. Halothane has been shown to increase diameter in canine middle cerebral arterial rings with intact endothelium, via a mechanism that involves either stimulation of particulate, but not soluble, guanylate cyclase or inhibition of cyclic GMP phosphodiesterase (Eskinder *et al.*, 1992). The mechanism for activation of particulate guanylate cyclase may involve halothane-mediated increases in membrane fluidity.

An interesting mechanistic clue is present in the observation that halothane caused cGMP-dependent vasodilation in endothelium-denuded rat aortas, and the effect was inhibited by methylene blue (a known inhibitor of guanylate cyclase) (Nakamura *et al.*, 1991). This finding suggests that the mechanism of vasodilation by halothane involves production of NO within vessels from a source other than endothelium. For example, prolonged exposure to inhalational anesthetics has been demonstrated to upregulate iNOS from macrophages along with eNOS from pulmonary endothelial cells (Zuo and Johns, 1997). NOS inhibition, dose dependently and reversibly, reduced the threshold for halothane anesthesia in the rat (Johns *et al.*, 1992), again suggesting a role for NO in inhalational anesthetic mechanisms. In addition, halothane increased cortical cGMP but not cGMP in the cerebellum (Nahrwold *et al.*, 1977), which is a region of high baseline NOS activity. We found that NOS inhibition prevented cerebral hyperemia to halothane, isoflurane, and N_2O in dogs under baseline pentobarbital anesthesia (McPherson *et al.*, 1993). A subsequent study showed that these inhibitory effects were reversible with L-arginine, supporting a direct role for NO in the mechanism of isoflurane-induced cerebral hyperemia (Moore *et al.*, 1994). Similar NO linkages have been reported for halothane-induced vasodilation in rats, using a pial vessel preparation (Koenig *et al.*, 1992). The discrepancy between *in vitro* data showing little or no role for NO in anesthetic induced hyperemia and the results *in vivo* that implicate NO is likely explained by the presence of nonvascular sources of NO in intact brain. In summary, NO is an important mediator of inhalational agent-induced cerebral vasodilation *in vivo*. The source of NO production likely involves several tissue types, including perivascular nerves, astrocytes, and/or parenchymal neurons.

Role of NO in Cerebrovasodilation from Hypoglycemia

Hypoglycemia causes cerebral vasodilation, which begins with the onset of EEG slowing and is maximal at the onset of isoelectric EEG. The mechanism of hypoglycemia-induced cerebral vasodilation is unknown; however, tissue acidosis, potassium efflux, and prostaglandin production have been excluded as primary mechanisms. We have tested the role of NO in hypoglycemia-induced cerebral hyperemia (Ichord *et al.*, 1994) and found that NOS inhibition attenuated the vascular response to systemic hypoglycemia in a regionally selective manner. During hypoglycemia, CBF increased maximally at the onset of EEG silence, and this was associated with an increase in cerebral oxygen utilization. However, administration of a nonspecific NOS inhibitor accelerated the onset of EEG dysfunction during hypoglycemia and blocked the rise in oxygen utilization that accompanied an isoelectric EEG. Administration of the same inhibitor dose did not alter the increase in CBF which ordinarily occurs during hypoxia, suggesting that the role of NO was specific for hypoglycemia-induced hyperemia. In summary, NO is an important controller of CBF during systemic hypoglycemia and facilitates coupling of CBF to the high energy needs of the brain.

NO and Control of Cerebral Blood Flow during Seizures

Seizures are relatively common sequelae of ischemia. Although NO is clearly an important mediator of the increased CBF that accompanies seizures (Faraci *et al.*, 1993), the role of NO in the genesis or propagation of seizure activity is controversial. Some studies have demonstrated that systemic administration of nonspecific or specific inhibitors of nNOS reduced the intensity of pharmacologically induced seizures in animals (Mulsch *et al.*, 1994). However, others have demonstrated that NOS inhibition worsened seizure intensity, suggesting a protective role for NO, at least for pharmacologically induced epilepsy (Maggio *et al.*, 1995). Some of the confusion in the literature has been resolved by the demonstration that although generalized NOS inhibition accentuated pharmacologically induced seizures, this was not observed when a specific nNOS inhibitor was administered (Penix *et al.*, 1994). Thus, it is speculated that inhibition of eNOS must limit blood flow during seizures and worsen seizure intensity, whereas limiting NO production from neurons has some therapeutic value.

NO and Cerebral Ischemia

In normal brain, NO is a nontoxic mediator of cerebral vasodilation and a neurotransmitter. However, converging evidence from many laboratories and experimental preparations indicates that NO is neurotoxic when present in abnormally high concentrations and is a significant threat by pro-oxidant mechanisms to neuronal integrity and function.

In contrast, diminished endothelial production of NO and the resulting loss of vasodilatory capacity and microvascular patency serve only to compromise perfusion within partially injured and recoverable tissue regions. Therefore, the net effect of NO during cerebral ischemia is dependent on a dynamic balance: direct neurotoxicity due to NO overload versus vascular defects due to NO deficiency. Similarly, the experimental and therapeutic value of inhibiting NOS and NO formation depends on this same balance. Using this simplistic framework, the role of NO in cerebral ischemic mechanisms and potential therapeutic implications are examined.

NO Production in Brain during Cerebral Ischemia

Increased NO production in association with global ischemia and reperfusion was first documented at micromolar concentrations with an NO electrochemical probe (Malinski *et al.*, 1993). More recently, we have used a microdialysis technique in conjunction with middle cerebral artery occlusion (MCAO) to estimate *in vivo* NO production in ischemic and reperfused brain. The brain region of interest (striatum) is loaded with L-[³H]arginine administered by microdialysis probe prior to MCAO, then the resulting [³H]citrulline is collected during ischemia and measured by ion-exchange chromatography (Bhardwaj *et al.* 1995, 1997a,b). The rate of [³H]citrulline production provides an estimate of NO production. Using this technique, we have shown increases in NO during MCAO and its persistence during early reperfusion (Toung *et al.*, 1999). Others have demonstrated an accumulation of stable oxidative NO metabolites (NO₂⁻ and NO₃⁻) within minutes of reperfusion that lasts for several hours in tissue extracts (Rao *et al.*, 1998) and in microdialysis samples (Togashi *et al.*, 1998). Thus measurements of accumulated, stable oxidative NO metabolites serve as a reasonable indicator of NOS activity over time. In focal ischemia, NO production can be limited in central ischemic regions due to the reduced availability of cofactors required for optimal NOS function (Ashwal *et al.*, 1998). Persistent changes in NOS activity have also been demonstrated in the rat fetal brain exposed to transient hypoxia-ischemia. After an initial increase in cerebral NOS activity, a substantial reduction in enzyme activity is observed that may last for days (Cai *et al.*, 1998). It must be emphasized that whereas each of these studies demonstrated that NO production increases during ischemia-reperfusion, the source of the NO was not determined. The presumption is that a large part of the NO "signal" in brain arises from neurons, via activation of nNOS. However, measurements of NO production over time likely contain a significant contribution from iNOS as well.

In addition to rapid increases in NO production, cerebral ischemia leads to an upregulation of nNOS (NOS I). Upregulation of nNOS mRNA may be a generalized response to neuronal stress and injury, as numerous chemical and biological agents result in enhanced nNOS expression. These include diverse stimuli such as pain, heat stress, axonal transection, colchicine treatment, immobilization stress, as well as hypoxia and ischemia. Enhanced nNOS expression

is frequently accompanied by induction of transcription factors such as *c-jun* and *c-fos*. Increases in mRNA for nNOS have been demonstrated after MCAO in the rat (Zhang *et al.*, 1994; Samdani *et al.*, 1997). Further, increased nNOS expression was demonstrated by 6–18 hours of reperfusion in dogs exposed to hypothermic circulatory arrest (Brock *et al.*, 1996).

Overproduction of local NO is also the consequence of marked iNOS induction in glia and inflammatory cells recruited to areas of injury. Increased expression of eNOS in brain vessels has also been reported within hours of global cerebral ischemia (Gajkowska and Mossakowski, 1997; Beasley *et al.*, 1998) and of traumatic brain injury in rat (Cobbs *et al.*, 1997). However, it is unclear if the protein is functional, because vasodilatory capacity in postischemic pial vessels is markedly impaired in many species. Further, CBF abnormalities after ischemic insult are well documented, including delayed hypoperfusion and impaired microvascular flow.

Mechanism of NO-Induced Toxicity

With the onset of ischemia and anoxic depolarization, excitatory neurotransmitter levels rise with overstimulation of postsynaptic receptors and associated ionotropic channels. It is hypothesized that, once released, excitatory amino acids cause an increase in postsynaptic intracellular calcium, which then causes an increase in NOS activity. NMDA glutamate receptors have been widely implicated as regulators of NO synthesis in this circumstance. Throughout neocortex, striatum, and hippocampus, nNOS immunoreactive neurons colabel for NMDAR1 receptor subunit protein and have a distinct NMDA receptor phenotype (Weiss *et al.*, 1998). NO release may further disrupt calcium homeostasis (Brorson and Zhang, 1997; Ohta *et al.*, 1997), and it may amplify persistent release of excitatory amino acids and spreading depression-like waves of depolarization. These spreading depression-like waves of depolarization and glutamate release correlate well with infarction size (Shimizu-Sasamata *et al.*, 1998). An essential component of NO toxicity is due to the propensity of the molecule to become highly reactive and toxic on conversion to more strongly oxidizing species. During reperfusion, oxygen radicals may be produced through mechanisms involving metabolism of free fatty acids, xanthine (Ratych *et al.*, 1987), and neutrophils (Hallenebeck *et al.*, 1986; Fabian and Kent, 1999; Yenari *et al.*, 1998; Soriano *et al.*, 1999). Although oxygen radicals themselves cause significant injury following transient cerebral ischemia (Fabian and Kent, 1999; Yenari *et al.*, 1998; Soriano *et al.*, 1999; Fujimura *et al.*, 1999; Li *et al.*, 1998; Kamii *et al.*, 1996; Yang *et al.*, 1994; Kinouchi *et al.*, 1991; Imaizumi *et al.*, 1990; Matsumiya *et al.*, 1991; Liu *et al.*, 1989), toxicity is greatly accentuated when they react with NO.

NO in high concentration likely reacts with the oxygen radical superoxide, forming peroxynitrite. Once produced, peroxynitrite causes increased membrane permeability to sodium and further neuronal leakage of excitatory amino acids

(Moro *et al.*, 1998). As discussed later in this chapter, peroxynitrite and protein nitration play important mechanistic roles in NO neurotoxicity.

NO and Postischemic Vascular Defects

If overproduction of NO and its pro-oxidant metabolites cause cell damage, then vascular sources of NO may participate in causing of endothelial damage and dysfunction after cerebral ischemia. However, as endothelial damage matures, NO production via eNOS may be compromised. Deficiency in NO production has been hypothesized to have significant effects on the ischemic and postischemic cerebral circulation. Altered NO has been implicated in the mechanism of postischemic transient hyperemia and delayed hypoperfusion (Greenberg *et al.*, 1995). Moskowitz *et al.* (1989) have demonstrated that postischemic hyperemia is attenuated by chronic trigeminal ganglionectomy, and they suggested that the mechanism of hyperemia is linked to transient neural stimulation of NOS and increased release of NO. More recently, NO has been more directly linked as a mechanism of postischemic hyperemia (Greenberg *et al.*, 1995; Humphreys and Koss, 1998).

During reperfusion from ischemia, particularly global cerebral ischemia, a period of delayed hypoperfusion is frequently observed in animal models. The phenomenon is characterized by depression of cerebral oxygen utilization and reduced blood flow to below preischemic values. The significance and mechanism for hypoperfusion are unclear, but it is likely that damage to vascular endothelium and consequent reduced vasodilatory capacity are important factors. Oxygen radicals such as superoxide anion participate in vascular injury, impairing NO synthesis. Further, superoxide anion avidly reacts with NO, resulting in its deactivation and loss of NO-mediated vasodilation during reperfusion. Therefore, two potential mechanisms for postischemic hypoperfusion include (1) a decreased tonic production of NO and (2) an aberration in NO signaling within the endothelium or vascular smooth muscle as NO is deactivated. We tested the first hypothesis that tonic release of NO was impaired by measuring CBF before and after intravenous administration of a nonspecific NOS inhibitor. We found that during profound hypoperfusion, NOS inhibition was still able to illicit a marked decrease in CBF (Clavier *et al.*, 1994a). In subsequent experiments, we examined the hypothesis that NO signaling was impaired during hypoperfusion by examining pial vessel responses to vasodilatory agonists in animals recovering from global cerebral ischemia. Consistent with this hypothesis, pial vasodilation to topically applied acetylcholine (which depends on endothelial NO production for its action) was grossly abnormal (Clavier *et al.*, 1994b). Defects in acetylcholine-induced vasodilatory responses were less pronounced in large pial arterioles ($201 \pm 11 \mu\text{m}$) than in medium ($66 \pm 2 \mu\text{m}$) or small ($35 \pm 2 \mu\text{m}$) arterioles, emphasizing that small vessel endothelial pathology is important. However, arteriolar dilation to nitroprusside (a direct donor of NO to vascular smooth muscle) was not

impaired (Clavier *et al.*, 1994b). These data suggest that defects in NO signaling are important in the pathology of hypoperfusion, and the defect is localized within the endothelium rather than in smooth muscle function.

Deficiency of Vascular NO and Ischemic Outcome

Loss of NO production within the vascular compartment furthers ischemic injury in brain regions that are at risk of inadequate perfusion but potentially salvageable (e.g., the penumbra in focal cerebral ischemia). Consistent with this hypothesis is the finding that nonspecific NOS inhibition with L-NAME (which inhibits all NOS isoforms, including eNOS) worsens injury in experimental stroke, whereas treatment with 7-nitroindazole (7-NI, a selective nNOS inhibitor) has no effect (Kamii *et al.*, 1996). Likewise, administration of a nonspecific NOS inhibitor as an ischemic treatment in nNOS null transgenic mice results in worsening of neurological injury (Huang *et al.*, 1994). Further, NO originating from eNOS has been clearly shown to benefit ischemic pathology because eNOS null mice show impaired cerebral hemodynamics during MCAO (Lo *et al.*, 1996). NO originating from eNOS (but not iNOS or nNOS) also appears to be required in the phenomenon of ischemic tolerance secondary to preconditioning (Gidday *et al.*, 1999).

With the knowledge that a reduction in eNOS-generated NO is detrimental in ischemia, several investigators have evaluated means of increasing NO availability to the vasculature or restoring eNOS activity during ischemia. One indirect method involves the administration of a superoxide anion scavenger, reducing available superoxide for reaction with NO. This strategy could have two benefits: first, removing a source of NO reactions and, second, reducing the toxic product of the reaction, peroxynitrite. In fact, combined treatment with a NOS inhibitor and a radical scavenger was demonstrated to provide synergistic protection from focal cerebral ischemia (Spinnewyn *et al.*, 1999). Successful scavenging of oxygen radicals following global ischemia was associated with increased accumulation of detectable NO (Shutenko *et al.*, 1999). Further, superoxide anion scavenging following transient global ischemia in piglets resulted in improved recovery of vascular reactivity to hypercapnia (Kirsch *et al.*, 1993).

The cholesterol-lowering agents 3-hydroxy-3-methylglutaryl-CoA reductase inhibitors have been demonstrated to selectively upregulate eNOS. Prophylactic treatment with 3-hydroxy-3-methylglutaryl-CoA reductase inhibitors improved cerebral perfusion, reduced brain injury, and improved neurological function in normocholesterolemic mice exposed to focal ischemia (Endres *et al.*, 1998). These benefits were not observed in eNOS null mice treated with the inhibitor, suggesting that the mechanism of protection was linked to NO generated from eNOS. Similarly, endogenous neuroprotectants such as estrogen work in part through vascular NO to improve intras ischemic perfusion and ameliorate ischemic damage in female animals (Hurn *et al.*, 1995; Palmon *et al.*, 1998; Alkayed *et al.*, 1998; Pelligrino *et al.*, 1998).

Gene therapy shows early promise as a means of overexpressing eNOS in vessels. Using replication-deficient viral vectors carrying a transgene for eNOS, vascular function can be improved in isolated rabbit carotid arteries (Ooboshi *et al.*, 1997; Kullo *et al.*, 1997). Vessels transfected with eNOS demonstrate improved vasodilation to acetylcholine and calcium ionophore (Ooboshi *et al.*, 1997), diminished contractile responses to vasoconstrictors such as phenylephrine, and increased *ex vivo* calcium dependent NOS activity (Kullo *et al.*, 1997). A similar approach has been viable in cerebral arteries. Transfection of eNOS via an adenoviral vector into canine basilar arteries increased basal cGMP production and reduced vasoconstriction in response to pharmacological agonists (Chen *et al.*, 1997). These benefits were readily reversible by nonspecific NOS inhibitors.

On the other extreme, a single investigation in stroke patients has assessed possible benefits of supplying NO to the cerebral circulation compromised by ischemia (Butterworth *et al.*, 1998). In this study, sodium nitroprusside was administered as an NO donor, with the dual objective of improving CBF distribution to the ischemic penumbra and inhibiting undesirable platelet aggregation and activation of adhesion molecules. Twenty-two patients with acute ischemic stroke and 12 control patients were treated with sodium nitroprusside at a dose that minimally depressed mean arterial pressure (i.e., by 10 mmHg). Although platelet function was not altered, three of four patients evaluated for cerebral perfusion sustained improved penumbral blood flow during drug administration.

An important question is whether eNOS abnormalities are important in genetically stroke-prone animals and in ischemic vulnerability. We have tested the hypothesis that altered NOS activity could account for the high occurrence of stroke in spontaneously hypertensive stroke-prone rats (SHRSP). Although endothelium-dependent, NO-mediated cerebral vasodilation was impaired in SHRSP rats, we observed no difference in regional brain NOS activity, or in degree of calcium dependence of NOS, as compared to their hypertensive or normotensive controls (Clavier *et al.*, 1994c). In addition, although salt loading and dietary manipulations predisposed these animals to stroke, it did not change cortical NOS activity. We also tested the hypothesis that predisposition to stroke is related to impaired regulation of NOS. We found no insensitivity to inhibition of NOS or depressed CBF response to pharmacological inhibition (Izuta *et al.*, 1995). Therefore, genetic predisposition to stroke in this animal model does not appear to have a link to NOS. Likewise, others have demonstrated a poor correlation in humans between stroke frequency and eNOS gene polymorphism (exon 7) (Markus *et al.*, 1998).

Blocking the Sources of NO Overproduction

The neuronal isoform is present in a small population of neurons; however, these neurons are distributed widely in the central nervous system. A variety of experimental paradigms have demonstrated that excessive NO derived from such neuronal sources increases early ischemic brain dam-

age. Inducible NO released by microglia and infiltrating inflammatory cells contributes in the later stages of neuronal injury. Much work in primary neuronal culture and in animal models offers confirmation at the cellular and organ level that NO neurotoxicity is a major injury mechanism in stroke and experimental brain injury. Assessing the toxicity of NO and the therapeutic value of pharmacological NOS inhibition *in vivo* has been slowed and confounded by the lack of isoform-specific inhibitors with good tissue penetration and which do not compromise CBF and vascular function via eNOS. Further, cerebral ischemia is a multifactorial pathology, and isolating NO-specific mechanisms remains a complex process. Parallel injury mechanisms frequently obscure many well-predicted results *in vitro* and *in vivo*. These mechanisms include primary mitochondrial failure, acidosis and cell swelling, sodium overload and loss of transmembrane ion gradients, eicosanoid elaboration, protease activation, and many non-NO-linked radical mechanisms. Nevertheless, key pieces of evidence implicate nNOS and iNOS as sources of NO toxicity and suggest therapeutic avenues (Nishikawa *et al.*, 1994).

Numerous *in vitro* studies indicate that NO is a major mediator of oxygen–glucose deprivation (OGD), as well as glutamate excitotoxicity. In primary cortical neuronal cultures, NO mediated the loss of cell viability after NMDA exposure. Further, treatment with agents that decrease NOS catalytic activity protected against NMDA excitotoxicity, including pharmacological NO or calcineurin inhibitors and agents that bind calmodulin (Dawson *et al.*, 1991, 1993) (for a review, see Samdani *et al.*, 1997). In addition, Izumi *et al.* (1992) have shown that NOS inhibitors applied to hippocampal slices prevent glutamate- and NMDA-mediated cell death, which was reversible by L-arginine. Cultures obtained from transgenic animals deficient in nNOS were demonstrated to be resistant to OGD as compared to cultures from wild-type mice (Dawson *et al.*, 1996).

In models of focal cerebral ischemia, significant NOS inhibition reduces infarction volume when agents are employed that either are nNOS selective or are given at concentrations that do not affect vascular NO production. These results extend across species, including rats, mice, and cats. Studies have utilized the selective nNOS inhibitor 7-NI, which has been useful in providing proof-of-principle but is of limited clinical utility owing to poor aqueous solubility. 7-NI has been shown to reduce injury in the setting of both focal (Yoshida *et al.*, 1994; Escott *et al.*, 1998; Coert *et al.*, 1999) and global forebrain ischemia (Nanri *et al.*, 1998). However, its therapeutic window is limited to approximately 60 min of onset of ischemia because of a lack of a parenteral preparation (Escott *et al.*, 1998).

In contrast, AR-R 17477 is one of a series of water-soluble, heterocyclic, substituted amidines that inhibits nNOS and reduces neurological injury when administered at the onset of reperfusion. At a dose of 1 mg/kg, histology was improved when assessed at 7 days postischemia in the rat (Z. G. Zhang *et al.*, 1996). However, careful dose–response relationships must be evaluated to understand the role of NOS inhibition. For example, higher doses of AR-R 17477

(Z. G. Zhang *et al.*, 1996) were not effective and caused a reduction in CBF and increased arterial blood pressure. These hemodynamic effects suggest dose-dependent, non-selective endothelial actions that could adversely affect penumbral blood flow. We have observed previously unreported effects on blood pressure even at 3 mg/kg of this agent in unanesthetized rats (Harukuni *et al.*, 1999). Our observations are in contrast to earlier studies conducted in halothane–nitrous oxide-anesthetized animals. These anesthetic agents are known to alter vascular tone by a mechanism that involves NO (Moore *et al.*, 1994; McPherson *et al.*, 1993) and may have direct effects on neuronal NOS (Tobin *et al.*, 1994; Rengasamy *et al.*, 1997). Therefore, the use of halothane–nitrous oxide anesthesia may have masked the effects of 3 mg/kg AR-R 17477 on peripheral vascular tone, which became evident in the unanesthetized state.

Conventional pharmacological approaches to the demonstration of the toxicity of NO have been demonstrated in transgenic animal models of focal cerebral ischemia. Infarction volume after permanent MCAO was reduced in neuronal NOS null mice as compared to age-matched wild-type controls (Huang *et al.*, 1994). Similarly, genetic deficiency in nNOS also resulted in improved histological outcomes from transient, reversible MCAO and from global cerebral ischemia (Hara *et al.*, 1996; Panahian *et al.*, 1996). It must be emphasized that although transgenic models are quite useful in the study of cerebral ischemia *in vivo*, these animals have lacked the gene (and enzyme) since birth and may demonstrate a compensatory physiology that is unique to the transgenic strain. Therefore, it is gratifying to note the good agreement between data from cultured cells, nNOS deficient mice, and pharmacologically inhibited animals, all of which clearly show the importance of NO neurotoxicity during ischemia and energy failure.

The importance of nNOS in the mechanism of brain injury following transient global cerebral ischemia is less clear. nNOS appears to be the isoform responsible for NO production during forebrain ischemia in gerbils (Lei *et al.*, 1999). Further, nNOS null mice have less injury to CA1 hippocampal neurons following 5 or 10 min of global ischemia (Panahian *et al.*, 1996). However, NO appears to increase more rapidly and reproducibly following focal ischemia in rats, as compared to global ischemia in gerbils (Araki *et al.*, 1998). Inhibition of NOS is neuroprotective in some (Nakagomi *et al.*, 1997; O'Neill *et al.*, 1997), but not all, rodent models of transient forebrain ischemia (Sancerrario *et al.*, 1994; Buchan *et al.*, 1994; Lei *et al.*, 1999). In an attempt to resolve these inconsistencies in rodent models, we tested the effect of a nonspecific NOS inhibitor (L-NAME) on neurological outcome in cats treated with transient global ischemia induced by aortic occlusion. Further, L-arginine administration was hypothesized to worsen neurological injury by increasing substrate availability for NO production (Kirsch *et al.*, 1997). We found that neither NOS inhibition nor L-arginine administration affected the intensity of ischemic insult (time to EEG silence during occlusion) and did not improve (or worsen) the neurological outcome. Ten minutes of global cerebral ischemia produced severe neurological injury in the

cat as measured either by standard neuropathology or by functional, neurological examination. Although reducing the ischemic duration to 5 min reduced the severity of histological injury, L-NAME treatment still remained ineffective. Therefore, it remains unclear if NO is important in global cerebral ischemic injury; however, our data in higher order animals do not support a role for NOS inhibition.

A newly identified protein with endogenous NOS inhibitory activity may also reduce NO toxicity. Regional neuronal responses to an ischemic event may be influenced by the amount of protein inhibitor of nNOS (PIN) produced concomitantly with NOS stimulation (Gillardot *et al.*, 1998). Following transient global ischemia, mRNA expression of the protein inhibitor of nNOS is more prevalent in brain regions that are resistant to ischemia-induced injury. There is also a progressive accumulation of PIN in cortical neurons that border the infarct region after MCAO. Another endogenous NO inhibitor has been detected in human plasma; circulating levels of asymmetric dimethylarginine have been correlated with carotid artery vascular pathology (Miyazaki *et al.*, 1999). These observations suggest new alternatives by which ischemic NO production could be potentially harnessed in brain. The therapeutic significance of endogenous NO inhibitors in cerebral ischemia requires further investigation.

Delayed Postischemic Injury due to Inducible NO Synthase Activity

Although iNOS is not detectable in healthy brain, NO is produced during reperfusion via iNOS in microglia and neutrophils that enter damaged brain as part of a postischemic inflammatory response (Bidmon *et al.*, 1998). These cells produce excessive NO for many hours after the onset of reperfusion (Iadecola *et al.*, 1995; Togashi *et al.*, 1998). Further, iNOS can be expressed in neurons, astrocytes, and endothelial cells under pathological conditions. iNOS immunoreactivity has been found in regions of ischemic human brain post mortem (Foster *et al.*, 1999). In rodents, functional iNOS protein can be identified within 12 hours of the ischemic insult, returning to baseline levels by approximately 7 days. Induction of iNOS results in delayed neuronal death *in vitro* and exacerbation of glutamate toxicity. Mice lacking the gene for iNOS do not express iNOS mRNA or protein after MCAO and accordingly have significantly smaller infarction volumes as compared to wild-type mice (Iadecola *et al.*, 1997).

There are important but complex interactions between iNOS and nNOS activity during experimental ischemia. One hypothesis is that the stimulus for iNOS induction and activity is nNOS-induced NO production (Higuchi *et al.*, 1998). Likewise, the finding that NMDA-induced excitotoxic brain lesions can be prevented by administration of the iNOS inhibitor aminoguanidine further suggests a relationship between nNOS-induced NO production and subsequent activation of iNOS (Lecanu *et al.*, 1998). In addition, protein kinase C has been found to be a major second messenger in

the signaling pathway regulating iNOS expression in microglia, which intriguingly opens the possibility for testing protein kinase C inhibitors in treating delayed postischemic neurological injury (Chen *et al.*, 1998; Fiebich *et al.*, 1998).

NO generated via iNOS supports postischemic inflammatory responses, in part through enhanced cyclooxygenase-2 (COX-2) activity, proinflammatory prostanoids, and reactive oxygen species (Nogawa *et al.*, 1998). Delayed sources of NO production (Yoshida *et al.*, 1995) and inhibition of iNOS are therapeutically important because the window for effective treatment is wide. Inhibition of iNOS can be beneficial even when inhibitor administration is delayed, for example, 24 hours after the onset of reperfusion (F. Zhang *et al.*, 1996).

Treatments that involve iNOS include aminoguanidine, heparin, agents which increase cAMP levels within brain, and tetracyclines. Systemic administration of the specific iNOS inhibitor aminoguanidine was associated with a dose-dependent reduction in brain injury when initiated 12 or 24 hours post-permanent MCAO in rat (Nagayama *et al.*, 1998). The efficacy of aminoguanidine has been shown to be dependent on prolonged administration, for example, for a minimum of 2 days following the onset of ischemia, suggesting prolonged NO production via iNOS which cannot be substantially altered by short-term drug treatment (Zhang and Iadecola, 1998). Likewise, it has been postulated that part of the benefit of heparin in treatment of ischemic stroke may be related to attenuation of iNOS expression and NO catalytic activity (Bonmann *et al.*, 1998). In addition, pharmacological agents that increase brain levels of cyclic AMP have been proposed as potential neuroprotectants. This is based on the finding that adenosine receptor agonists [particularly adenosine A3 receptor agonists (von Lubitz *et al.*, 1999)], forskolin, and dibutyryl cyclic AMP all result in increased brain cyclic AMP and inhibition of iNOS expression and activity (Brodie *et al.*, 1998). Lastly, the tetracyclines minocycline and doxycycline have anti-inflammatory effects that are independent of their antibacterial effects. The tetracycline family may prevent microglial caspase induction, which is associated in turn with a substantial reduction in iNOS mRNA in postischemic gerbil brain (Yrjanheikki *et al.*, 1998).

Downstream Mechanisms of NO Toxicity

The precise pathway by which NO kills neurons in culture during OGD and as a consequence of *in vivo* cerebral ischemia is not known. Oxidant mechanisms have been clearly implicated, although NO per se is not a strong oxidant. A central component of the mechanism is the propensity of NO at high concentrations to react with superoxide anion and form peroxynitrite anion, which decomposes at acidic pH into hydroxyl radical and nitrogen dioxide (Beckman *et al.*, 1990; Beckman, 1990). More importantly, peroxynitrite persists in part as an activated complex with great oxidizing potential and important cellular targets such as DNA and cytoskeletal proteins (for review, see Beckman and

Koppenol, 1996). Consistent with the NO–peroxynitrite hypothesis, immunohistochemical staining for nitrotyrosine (a marker for oxidants derived from NO such as peroxynitrite) increases during transient ischemia and is reduced by non-selective NOS inhibitors (Forman *et al.*, 1998). Peroxynitrite or ONOO[−] is a potent oxidant, although somewhat selective due to its relatively slow rate of reaction with many biological molecules. Evidence from several laboratories suggests that many toxic effects associated with NO are, in fact, due to ONOO[−] toxicity. For example, one of the targets of ONOO[−] is the mitochondrial form of superoxide dismutase (manganese SOD or MnSOD). Therefore, ONOO[−] inactivation of MnSOD may result in enhanced oxidant injury within mitochondria due to impaired scavenging capacity. Reduced MnSOD activity exacerbates glutamate injury in mouse cortical cultures and is important in preventing injury after focal cerebral ischemia, potentially by blocking cytosolic redistribution of mitochondrial enzyme cytochrome *c* (Fujimura *et al.*, 1999; Li *et al.*, 1998).

There are additional mechanisms of the toxicity of NO. When arginine is of limited availability (as in ischemia), nNOS can transfer electrons from NADPH to oxygen and form superoxide. Therefore, besides synthesizing NO, nNOS can produce superoxide at low concentrations (Xia *et al.*, 1996). However, it is not clear to what extent this source of superoxide is biologically important in cerebral ischemic injury. Because NO reacts readily with iron–sulfur cluster-containing proteins, another deleterious effect may be inhibition of mitochondrial enzymes such as NADH–ubiquinone oxidoreductase and NADH:succinate oxidoreductase. NO also inhibits mitochondrial respiration by competing with oxygen at the level of cytochrome oxidase.

One pathway of NO-mediated cell damage is via activation of the enzyme poly(ADP-ribose) polymerase (PARP), also known as poly(ADP-ribose) synthetase. PARP is an abundant nuclear enzyme that helps to maintain genomic integrity in neurons and numerous other cell types. Although the sensing mechanism is not clear, PARP is activated by DNA strand nicks or tears resulting from a variety of cell stressors, including oxidant and free radical attack during reperfusion after intense ischemia. The physiological function of PARP, and of poly(ADP-ribosylation), is under heavy ongoing investigation, but a likely role is to assure correct processing of DNA breaks and to prevent undesirable DNA recombination reactions. Data from our laboratory and others indicate that PARP is a powerful player in neuroinjury from experimental stroke and may be a key downstream mechanism for NO toxicity.

NO and peroxynitrite damage DNA and thus activate PARP. Once activated, PARP catalyzes the transfer of ADP-ribose units from NAD to nuclear proteins. The reaction consumes NAD in the process, and ultimately ATP as well, because NAD regeneration within the cell requires ATP. Hypothetically, intense PARP activation, such as would be likely to occur in the presence of ischemia-damaged DNA, utilizes ATP at a time when cellular energy stores are limited. Excessive PARP activation can also occur as a result of re-

lease of intracellular calcium stores (Tasker *et al.*, 1998). The finding that PARP immunostaining was rapidly increased during reperfusion from focal ischemia is consistent with this hypothesis (Endres *et al.*, 1997). Further, administration of either NOS or PARP inhibitors resulted in reduced poly(ADP-ribosylation) and infarction volume after transient focal cerebral ischemia (Tokime *et al.*, 1998). Likewise, mice with genetic disruption of PARP were greatly protected against glutamate toxicity and sustained a decreased infarction volume following transient MCAO, as compared to wild-type mice of the same background strain (Eliasson *et al.*, 1997). During ischemia, NAD was less severely depleted in PARP-deficient transgenics, and this finding was accompanied by a reduced overall infarction size but little change in apoptotic markers within the ischemic zone (Endres *et al.*, 1997). Pharmacological inhibition of PARP with 3-aminobenzamide produces decreased infarction volume (Endres *et al.*, 1997; Lo *et al.*, 1998). Further, other DNA repair enzymes such as apurinic/apyrimidinic endonuclease may be critical to repair of neurons after ischemia, rather than cell destruction as is the case with PARP (Edwards *et al.*, 1998; Kawase *et al.*, 1999; Fujimori *et al.*, 1999). Therefore, controlling downstream mechanisms of NO toxicity and developing specific PARP inhibitors with good brain penetration will be potential therapeutic avenues in the future.

Role of Nitric Oxide in Neuronal Protection versus Apoptosis

Stuart A. Lipton

Center for Neuroscience and Aging, The Burnham Institute, La Jolla, California; and The CNS Research Institute, Brigham and Women's Hospital, and Program in Neuroscience, Harvard Medical School, Boston, Massachusetts

VARIOUS NITRIC OXIDE (NO)-RELATED REDOX SPECIES ARE CHARACTERIZED BY DISTINCT CHEMICAL REACTIVITIES THAT DIFFERENTIALLY INFLUENCE THE LIFE AND DEATH OF NEURONS IN RESPONSE TO VARIOUS INSULTS. IN THE CASE OF NO^+ EQUIVALENTS (HAVING ONE LESS ELECTRON THAN NO^\bullet), THE MECHANISM OF REACTION OFTEN INVOLVES S-NITROSYLATION OR TRANSFER OF THE NO GROUP TO CYSTEINE THIOL (OR MORE PROPERLY THIOLATE ANION) TO FORM AN RS-NO; FURTHER OXIDATION OF CRITICAL THIOLS CAN POSSIBLY THEN FORM DI-SULFIDE BONDS FROM NEIGHBORING CYSTEINE RESIDUES. INCREASING EVIDENCE, BOTH PHYSIOLOGICAL AND CHEMICAL, SUGGESTS THAT THE ACTIVITIES OF THE *N*-METHYL-D-ASPARTATE (NMDA) SUBTYPE OF GLUTAMATE RECEPTOR AND CASPASE ENZYMES CAN BE DECREASED BY S-NITROSYLATION, AS CAN OTHER SIGNALING MOLECULES INVOLVED IN NEURONAL APOPTOTIC PATHWAYS, TO AFFORD NEUROPROTECTION. LEFT UNCURBED, OVERSTIMULATION OF THE NMDA RECEPTOR (NMDAR) LEADS TO EXCESSIVE Ca^{2+} INFLUX AND ACTIVATION OF A VARIETY OF NEURODESTRUCTIVE PATHWAYS INCLUDING NO^\bullet GENERATION, WHICH LEADS TO APOPTOSIS, IF THE INITIAL INSULT IS MILD, OR NECROSIS, IF MORE SEVERE.

OVER THE PAST DECADE, BEGINNING WITH AN INITIAL REPORT ON THE NMDAR, EVIDENCE HAS ACCUMULATED THAT S-NITROSYLATION CAN REGULATE THE BIOLOGICAL ACTIVITY OF A GREAT VARIETY OF PROTEINS. IN SOME WAYS THIS REACTION IS AKIN TO PHOSPHORYLATION, MYRISTOYLATION, PALMITOYLATION, ETC., BUT IN OTHER ASPECTS S-NITROSYLATION HAS BROADER IMPLICATIONS FOR AUTOCRINE AND PARACRINE SIGNALING BECAUSE THE REACTION CAN OCCUR EITHER INTRACELLULARLY (AS ON CASPASES) OR EXTRACELLULARLY (AS IN THE CASE OF THE NMDAR). THUS, THIS CHEMICAL REACTION IS GAINING ACCEPTANCE AS A NEWLY RECOGNIZED MOLECULAR SWITCH TO CONTROL PROTEIN FUNCTION VIA REACTIVE THIOL GROUPS, SUCH AS THOSE ENCOUNTERED ON THE NMDAR AND IN THE ACTIVE SITE OF CASPASES.

ONE METHOD OF PRODUCING S-NITROSYLATION OF THE NMDAR AND CASPASES IS THE ADMINISTRATION OF NITROGLYCERIN. NITROGLYCERIN CAN BE NEUROPROTECTIVE IN ACUTE FOCAL ISCHEMIA-REPERFUSION MODELS VIA MECHANISMS OTHER THAN INCREASING CERE-BRAL BLOOD FLOW. IN CONTRAST, NO^\bullet ITSELF DOES NOT APPEAR TO REACT WITH THIOL UNDER PHYSIOLOGICAL CONDITIONS. IN FACT, THE FAVORED REACTION OF NO^\bullet WITH O_2^- (SUPEROXIDE ANION) TO FORM HIGH CONCENTRATIONS OF ONOO^- (PEROXYNITRITE) LEADS TO NEUROTOXICITY. A THIRD NO-RELATED SPECIES WITH ONE ADDED ELECTRON COMPARED TO NO^\bullet IS NITROXYL ANION (NO^- , WHICH MAY EXIST IN BOTH SINGLET AND TRIPLET STATES). NO^- —UNLIKE NO^\bullet BUT REMINISCENT OF NO^+ TRANSFER—CAN ALSO REACT EITHER DIRECTLY (IN THE SINGLET STATE) OR INDIRECTLY (IN THE TRIPLET STATE, VIA FORMATION OF VERY LOW CONCENTRATIONS OF ONOO^-) WITH CRITICAL THIOL GROUPS OF THE NMDAR AND MAY THUS ACT TO CURTAIL EXCESSIVE Ca^{2+} INFLUX AND PROVIDE NEUROPROTECTION FROM EXCITOTOXIC INSULTS.

Introduction: S-Nitrosylation to Regulate Protein Function

Redox modulation by covalent modification of sulfhydryl (thiol) groups on protein cysteine residues can regulate protein function. If they possess a sufficient redox potential, oxidizing agents can react to form adducts on single sulfhydryl groups, or, if two free sulfhydryl groups are vicinal (in close proximity), disulfide bonds may possibly be formed. Reducing agents can regenerate free sulfhydryl (-SH) groups by donating an electron(s). One example of a protein possessing the potential for physiological regulation by redox agents is the NMDAR; another is the family of caspase enzymes, which have a critical cysteine residue in their active site. The redox modulatory sites of the NMDAR consist of critical cysteine residues which, when chemically reduced, increase the magnitude of NMDA-evoked responses. In contrast, after oxidation, NMDA-evoked responses are decreased in size.

Considering endogenous redox agents, in addition to the usual suspects including glutathione, lipoic acid, and reactive oxygen species, nitric oxide-related species have more recently come to the fore. This has occurred largely because of the rediscovery and application to biological systems of work from the early part of the twentieth century showing the organic synthesis of nitrosothiols (RS-NO) (Stamler *et al.*, 1992a). NO-related species include nitric oxide (NO \cdot) and nitrosonium ion equivalents (NO $^+$), with one less electron than NO \cdot , as well as nitroxyl anion (NO $^-$) with one additional electron compared to NO \cdot (Stamler *et al.*, 1992b). Recent evidence suggests these redox-related forms, or their functional equivalents, are important pharmacologically and physiologically, participating in distinctive chemical reactions.

NO $^+$ can be transferred (not as free NO $^+$ but as an intermediate that functionally donates NO $^+$) from either endogenous or exogenous donors to thiol. This reaction is termed S-nitrosylation and forms nitrosothiols; for example, we believe they are formed on the NMDAR (NMDAR-SNO). The reaction of the NO group with NMDAR thiol decreases NMDA-evoked responses similar to an oxidizing agent. A consensus motif of amino acids composed of nucleophilic residues surrounding a critical cysteine, which increases the susceptibility of the cysteine sulfhydryl to S-nitrosylation by NO $^+$ donors, has been proposed (see below). NMDAR subunits contain multiple typical consensus motifs for S-nitrosylation (Stamler *et al.*, 1997), and site-directed mutagenesis work on recombinant NMDAR subunits indicate that these cysteine residues indeed react with NO $^+$ donors, but only if the cysteine residues are in the reduced (free sulfhydryl) state. NO $^-$ in its singlet or high-energy state can also react with thiol, for example, on the NMDAR (Lipton and Stamler, 1994). However, NO \cdot in general will not react with thiol; instead, it can lead to a neurodestructive pathway via reaction with O $_2^-$ to form ONOO $^-$ (peroxynitrite) (Beckman *et al.*, 1990; Dawson *et al.*, 1993; Lipton *et al.*, 1993). This review sum-

marizes these processes and the evidence for and against their existence in the nervous system.

Reactive Nitrogen Intermediates as Physiological Messengers or Pathological Mediators of Apoptosis and Necrosis

Reactive nitrogen intermediates (RNI) are generated by the progressive oxidation of the terminal guanidine residue of L-arginine by nitric oxide synthase (NOS) to produce the NO group, although the exact NO-related species generated is still contentious. Further oxidation leads ultimately to nitrate, with RNI including NO $_2$, N $_2$ O $_3$, N $_2$ O $_4$, and physiological NO adducts such as S-nitrosothiols and peroxynitrite. Three different forms of NOS have been identified, two of which are constitutive and occur in neurons, namely, nNOS (or NOS1) and eNOS (or NOS3; eNOS was originally cloned from endothelial cells). Inducible NOS (iNOS or NOS2) occurs in the nervous system in astrocytes and microglia. The constitutive forms of NOS are activated by Ca $^{2+}$ via calmodulin.

The NO group has a dual role as physiological messenger and as a contributor to lethal processes. Classically, "NO" mediates endothelium-dependent relaxation, takes part in neurotransmission, and is a key player in the cellular immune response (Dawson *et al.*, 1992). Multiple reactions occur between oxygen, superoxide, and transition metals with the following products: N $_2$ O $_3$ [equivalent to (NO $_2^-$)(NO $^+$)], peroxynitrite (OONO $^-$), and metal-NO adducts, respectively. These reactions determine the biological activity of the NO group in its various redox-related forms. Other reactions involving the transfer of NO $^+$ equivalents (with one less electron than NO) result in nitrosative reactions at nucleophilic centers with critical cysteine sulfhydryls, producing S-nitrosothiol formation. This reaction, termed S-nitrosylation, occurs preferentially at specific consensus motifs of amino acid residues centered around a critical cysteine sulfhydryl that reacts with the NO group, and it serves to regulate protein function akin to phosphorylation of critical serine, threonine, or tyrosine residues (Stamler *et al.*, 1992b, 1997; Lipton *et al.*, 1993). Accordingly, thiol- and transition metal-containing proteins serve as major target sites for NO-related species (Stamler, 1994). NO-target interaction achieves both cGMP-dependent and cGMP-independent transducing mechanisms. Cyclic GMP-independent NO-induced responses account for the antimicrobial, the cytostatic, and in many cases the cytotoxic capacity of NO-related species. Excess production of NO \cdot has been shown to underlie, at least in part, glutamate-induced neuronal toxicity in cultures of cortical and striatal neurons (Dawson *et al.*, 1991). Finally, radicals generated by the interaction of NO \cdot with oxygen species can induce DNA damage (Noronha-Dutra *et al.*, 1993). This may activate poly(ADP-ribose) polymerase (PARP), which in turn consumes ATP, thus depleting energy stores and resulting in necrosis from a fail-

ure of homeostatic mechanisms (Zhang *et al.*, 1994). Our own studies have focused on the cytotoxicity of nitric oxide in conjunction with reactive oxygen species in cerebrocortical neurons.

NO-Induced Neuronal Cell Death: Contribution to Apoptosis

Excessive activation of excitatory amino acid receptors and the subsequent generation of free radical species have been implicated as a mechanism for neurotoxicity in both acute and chronic neurological diseases, ranging from stroke, epilepsy, and head trauma to Alzheimer's disease, amyotrophic lateral sclerosis, Huntington's disease, HIV-associated dementia, and glaucoma (Rothman and Olney, 1987; Choi, 1988; Meldrum and Garthwaite, 1990; Coyle and Puttfarcken, 1993; Lipton and Rosenberg, 1994; Dreyer and Lipton, 1999). This form of neuronal cell death has been termed "excitotoxicity" by John Olney. The underlying process responsible for neuronal cell death after overactivation of glutamate receptor subtypes—of which the NMDAR plays a prominent role because of its high permeability to Ca^{2+} —have only recently begun to be clarified. In a wide variety of neurologic disorders, excitotoxicity may be related to excessive glutamate release and/or lack of clearance, which results in excessive stimulation of NMDARs (Lipton and Rosenberg, 1994). This can result in either an acute or chronic process, possibly dependent on the level of NMDAR stimulation and NO/peroxynitrite generation (Bonfoco *et al.*, 1995). Other excitatory amino acid receptor subtypes also contribute to these processes, but in many cases the NMDAR has a prominent role.

The interaction of glutamate with excitatory amino acid receptors initiates a cascade of events involving excessive Ca^{2+} entry and activation of several enzymes, including phospholipases, proteases, and NOS (Rothman and Olney, 1987; Choi, 1988; Meldrum and Garthwaite, 1990; Coyle and Puttfarcken, 1993; Lipton and Rosenberg, 1994). Phospholipase A_2 activation leads to the generation of arachidonic acid and other metabolites as well as to the formation of oxygen free radicals. This can lead to a combination of oxidative and nitrosative stress, culminating in peroxynitrite formation and neuronal cell death (Beckman *et al.*, 1990; Lipton *et al.*, 1993). The cell death pathway can be either necrotic or apoptotic, depending on the intensity of the insult (Bonfoco *et al.*, 1995). To show this, we investigated whether apoptosis or necrosis can be induced in cerebrocortical neurons in culture by overstimulation of glutamate receptors, with consequent influx of excessive Ca^{2+} and downstream production of $\text{NO}\cdot$ and O_2^- . We used high and low concentrations of glutamate agonists (such as NMDA), NO donors [such as 3-morpholinodisulfonamide (SIN-1) and S-nitrosocysteine (SNOC)], or peroxynitrite. We found that exposure of cortical cultures to relatively short durations or low concentrations of NMDA, SNOC, SIN-1, or peroxynitrite induced delayed neuronal cell death characterized by apoptotic features. In contrast, intense exposure to high con-

centrations of NMDA or peroxynitrite induced relatively rapid necrotic cell death in neurons (Bonfoco *et al.*, 1995). Superoxide dismutase (SOD) and catalase attenuated neuronal cell death, most likely by reducing the formation of peroxynitrite, as they were only effective if peroxynitrite had not yet formed. These findings suggest that the intensity of the original insult may determine the ensuing pathway to either necrotic or apoptotic neuronal cell death. The nature of the original insult as well as the decision to enter the necrotic versus the apoptotic pathway might have therapeutic implications in terms of the possible effectiveness of SOD/catalase or NMDAR antagonists, as well as the necessary timing of such interventions.

High concentrations of NO (2 μM or more) have also been reported to disrupt mitochondrial respiration as well as glycolysis, leading to severe ATP depletion. Such profound alteration in ATP would likely result in necrosis (Brorson *et al.*, 1999). However, NO can also lead to altered Ca^{2+} homeostasis and mitochondrial depolarization, events that have been linked to apoptosis (Ankarcrona *et al.*, 1995; Bonfoco *et al.*, 1995).

NO and Inhibition of Cell Death

In addition to the contribution of NO to neuronal cell death described earlier, it is important to outline the mechanisms whereby NO-related species can also be neuroprotective. Recent work has suggested that S-nitrosylation of critical cysteine thiol groups of a modulatory site(s) of the NMDAR, of p21ras during MAP kinase signaling, and of the active site of caspase enzymes can decrease the activity of these proteins, thereby contributing to neuroprotection. For example, curtailing excessive activity of the NMDAR by S-nitrosylation (transfer of NO^+ to protein thiol), or by reaction of thiol with nitroxyl anion (NO^-), can be neuroprotective (Lipton *et al.*, 1993; Lipton and Stamler, 1994; Stamler *et al.*, 1997; Kim *et al.*, 1999). Similarly, downstream from NMDAR activation, S-nitrosylation of a critical cysteine residue in p21ras, or of the cysteine residue in the active site of all known caspase enzymes, decreases their activity and also affords protection to neurons from NMDAR-mediated apoptotic events (Melino *et al.*, 1997; Tanneti *et al.*, 1997; Yun *et al.*, 1998). The activity of other proteins involved in apoptosis may also be affected by S-nitrosylation, such as that of transglutaminase (Melino *et al.*, 1997). Thus, depending on its redox state, the NO group can contribute to excitotoxicity (via formation of peroxynitrite in conjunction with superoxide anion) or can provide neuroprotection in at least some types of neurons (by downregulating the activity of both the NMDAR and its downstream activation of p21ras and caspases). Caspases in a variety of other cell types have also been shown to undergo S-nitrosylation (Dimmeler *et al.*, 1997; Kim *et al.*, 1997; Mannick *et al.*, 1999).

Besides directly inhibiting p21ras and caspases, NO may interfere with the execution of apoptosis at different steps, without necessarily affecting the rate of cell death, for example, by changing the mode of demise from apoptosis to

necrosis (Melino *et al.*, 1997). NO can inhibit caspase activation by mechanisms in addition to S-nitrosylation, for example, by NO-dependent formation of cGMP, which in some cell systems can interfere with cell death signaling upstream from caspase activation (Mannick *et al.*, 1994; Kim *et al.*, 1997; Hebestreit *et al.*, 1998). Moreover, since a well-documented action of NO is inhibition of the mitochondrial respiratory chain, it seems conceivable that the resulting ATP depletion might be relevant to the effects of NO on cell death. In fact, recent results have suggested that NO might prevent caspase activation by inhibiting mitochondrial respiration, and thereby lowering intracellular ATP levels (Leist *et al.*, 1999). The prevention of cell death in this system is only ephemeral. Cell demise is delayed, and doomed cells die eventually by necrosis. When nonmitochondrial, glycolytic ATP generation was supported via glucose supplementation to the culture medium, death reverted to its apoptotic form.

In vivo, halting the apoptotic program may have two possible implications: (i) neurons protected by NO via stopping the apoptotic execution cascade would have time to recover from a transient or mild insult, and thus survive; or (ii) neurons exposed to a lethal, normally apoptotic insult would eventually lyse without being removed by phagocytosis. Thus, depending on the situation, endogenous mediators, such as NO-related species, either may prevent cell demise entirely or convert an apoptotic insult into a necrotic one. In the latter case, the release of factors from dead cells and the ensuing inflammation could further aggravate tissue damage.

Cysteine Thiols React with NO-Related Species

As alluded to earlier, many of the neuroprotective actions of NO are mediated by S-nitrosylation of proteins critical for neuronal survival. A key question in determining the life or death outcome for cells concerns the mechanism and conditions that favor these nitrosylation reactions. This section outlines some of those conditions. Free endogenous nitrosium ion (NO^+) exists only at low pH. However, functional equivalents of NO^+ can be transferred to thiol, or, more properly perhaps, thiolate anion (RS^-), at physiological pH. For example, transfer of NO^+ equivalents occurs from one nitrosothiol to another, a reaction termed transnitrosylation, that is, $\text{R-SH} + \text{R}'\text{-SNO} \rightarrow \text{R-SNO} + \text{R}'\text{-SH}$. Since transfer of NO^+ involves thiolate anion (RS^-), it is pH dependent (Arnette and Stamler, 1995). Endogenous nitrosothiols, such as S-nitrosoglutathione, have been demonstrated to react in this manner and to exist in brain and in lung at concentrations approaching tens of micromolar (Arnette and Stamler, 1995; Hogg *et al.*, 1996; Kluge *et al.*, 1997). Additionally, evidence has shown that nNOS can, in conjunction with glutathione, produce S-nitrosoglutathione (Mayer *et al.*, 1998), an NO^+ equivalent and endogenous donor. The enzymatic machinery underlying the formation and breakdown of nitrosothiols is just beginning to be characterized. For example, thioredoxin reductase was shown to

catalyze the homolytic cleavage of nitrosothiol (R-SNO) to nitric oxide ($\text{NO}^\bullet + \text{RS}^\bullet$) (Nikitovic and Holmgren, 1996).

Classically, there was no precedent for direct reaction of NO^\bullet with thiols under anaerobic conditions (Pryor and Lightsey, 1981; Pryor *et al.*, 1982). However, Ischiropoulos and co-workers reported that under particular conditions, for example, in the presence of an electron acceptor such as O_2 , NO^\bullet could react with thiol to form a nitrosothiol (Gow *et al.*, 1997). However, this reaction may have been artificially facilitated by nominal amounts of copper that contaminated the solutions (J. Beckman, personal communication, 1998). Thus, most authorities agree that the reaction of NO^\bullet with thiol does not proceed directly. In fact, the reaction of NO^\bullet and O_2^- to form peroxynitrite is kinetically favored if both of these reactants are present (Beckman, 1994).

The next important concept in considering the chemical biology of reactions of the NO group involves our image of the local diffusion and ephemeral nature of NO^\bullet . Bredt and colleagues demonstrated that nNOS is located in close proximity to the NMDAR by virtue of the PDZ domain of nNOS (Brenman *et al.*, 1996). nNOS interacts via its PDZ domain with the carboxyl-terminal tail of NR1, the subunit of the NMDAR that is essential for functional activity. Therefore, NO group production occurs very near one of its potential targets, the NMDAR. With this localization, restricted diffusional constraints and the need for high local concentrations to facilitate NO reactions should not present a problem.

With some of the chemical reactions of these NO-related species in hand, we now turn our attention to the mechanism of S-nitrosylation or transfer of the NO moiety to cysteine sulfhydryl groups on the NMDAR. In the 7 years since we first proposed that S-nitrosylation can modulate protein function using the NMDAR as the archetypal protein (Lipton *et al.*, 1993), S-nitrosylation has also been shown to regulate the activity of various other ion channels, G proteins, growth factors, enzymes, and transcription factors (Stamler *et al.*, 1997). These reactions of NO-related species do not involve the well-known activation of guanylate cyclase by reaction with the heme group to increase cGMP formation. Rather, they involve reactions with cysteine sulfhydryls on an increasing number of protein targets to provide modulation of function, analogous to phosphorylation of critical serine, threonine, or tyrosine residues. S-Nitrosylation may be more versatile than phosphorylation in regulating protein activity since S-nitrosylation can occur on either extracellular or intracellular cysteine sulfhydryl groups, whereas phosphorylation and similar posttranslational events are exclusively intracellular. For example, the critical cysteine sulfhydryls on the NMDAR that react with the NO group are all located extracellularly (Choi *et al.*, 2000; Kim *et al.*, 1999). Moreover, the chemical reactivity of NO-related species is related to the local redox milieu and peptide environment, pH, temperature, and the presence of catalytic amounts of transition metals.

Previously, we had suggested that reaction of the NO group with regulatory sulfhydryl(s) of the redox modulatory site(s) of NMDAR results in downregulation of receptor ac-

tivity (Lipton *et al.*, 1993). In addition to our group, other groups had also shown that NO donors could decrease NMDAR function (Lei *et al.*, 1992; Manzoni *et al.*, 1992; Manzoni and Bockaert, 1993), but the exact mechanism of the reaction has remained contentious (Fagni *et al.*, 1995). The redox basis for this reaction will be presented below for both endogenous and recombinant NMDARs.

S-Nitrosylation, NMDAR Activity, and Neuroprotection

We and others reported that the NO group can decrease NMDAR activity (Hoyt *et al.*, 1992; Lei *et al.*, 1992; Manzoni *et al.*, 1992). We have shown that this reaction of NO occurs at a redox modulatory site(s) of the receptor, consisting of critical cysteine sulfhydryls or thiol groups (Lei *et al.*, 1992; Lipton *et al.*, 1993; Kohr *et al.*, 1994; Sullivan *et al.*, 1994). Interestingly, in recombinant NMDARs, not all redox sites (defined as cysteine residues that react with redox agents) of the NMDAR react with the NO group, just a subset of such cysteines (Choi *et al.*, 2000; Kim *et al.*, 1999).

In native neurons (e.g., cerebrocortical and retinal ganglion cells), we measured the amplitude of NMDA-evoked responses, monitored by whole-cell and single-channel recording with a patch electrode or by digital calcium imaging with the Ca^{2+} -sensitive dye fura-2 (Lei *et al.*, 1992; Lipton *et al.*, 1993). We found that sulfhydryl-reducing agents such as dithiothreitol (DTT), which promote the formation of free thiol groups, increased NMDA responses, predominantly by increasing the opening frequency of NMDAR-operated channels. In contrast, oxidizing agents such 5,5'-dithio (2-bisnitrobenzoic acid) (DTNB) decreased NMDA responses, by forming thiobenzoate protein conjugates at single sulfhydryl groups or perhaps by facilitating disulfide bond formation. In addition to the DTT and DTNB results, we knew that thiols on the NMDAR were involved because under our conditions *N*-ethylmaleimide (NEM), a relatively specific agent for alkylating thiols, irreversibly blocked the effects of these redox reagents while itself slightly decreasing responses to NMDA (Lei *et al.*, 1992; Lipton *et al.*, 1993). Importantly, under our specific conditions, NEM also prevented the subsequent effects of NO donors, indicating that reactions of thiol and NO groups were involved. Both our group and that of Joël Bockaert (Manzoni and Bockaert, 1993) have also demonstrated that endogenous production of NO can decrease NMDAR activity, indicating the potential physiological importance of this effect. In these experiments implicating the involvement of endogenous NO, inhibition of NOS was found to enhance subsequent NMDAR responses. Heretofore, however, there has not been universal consensus on the mechanism of action of NO in this system.

As an example of an NO^+ chemical reaction at the NMDAR, we found that *S*-nitrosocysteine decreases NMDAR activity as demonstrated by whole-cell recording

or by digital calcium imaging (Lipton *et al.*, 1993). During single-channel recording, *S*-nitrosocysteine (SNOC) decreased the opening frequency of NMDAR-operated channels in outside-out patches from cerebrocortical neurons (Lipton *et al.*, 1998). In the presence of copper, zinc-superoxide dismutase (Cu,Zn-SOD), SNOC attenuated NMDA-evoked Ca^{2+} influx, a prerequisite for NMDAR-mediated neurotoxicity. Not surprisingly, therefore, under the same conditions, application of SNOC ameliorated NMDAR-mediated neurotoxicity. These findings can be explained best by SNOC donating NO^+ equivalents. Thus, *S*-nitrosylation or facile transfer of an NO^+ equivalent to thiol groups of the NMDAR results in a nitrosothiol derivative of the NMDAR, which decreases receptor activity. Under these conditions, any NO^+ produced by alternative homolytic cleavage of SNOC is prevented from entering a neurotoxic pathway of ONOO^- formation via reaction with O_2^- because of the presence of excess SOD (Lipton *et al.*, 1993; Lipton and Stamler, 1994). Rather, NO group transfer leads to downregulation of NMDAR activity, possibly through facilitation of disulfide formation. The fact that EDTA can prevent the effects of the NO group on NMDAR activity (Fagni *et al.*, 1995) supports rather than refutes this chemistry. In particular, metals can facilitate nitrosative reactions involving NO^+ and O_2 (Stamler *et al.*, 1992b; Lipton *et al.*, 1996). In general, nitrosation of redox sites is facilitated by oxygen, transition metals, and perhaps O_2^- (Stamler, 1994; Gow *et al.*, 1997). The common event is the transfer of an NO^+ equivalent or another intermediate with NO^+ -like character to form an RS-NO , in this case on the NMDAR.

S-Nitrosylation of Recombinant NMDARs

In order to better understand redox mechanisms postulated to exist based on the previously mentioned experiments on primary neurons with native NMDARs, we have turned to recombinant systems. Our work on *S*-nitrosylation and other redox reactions of recombinant NMDARs in the *Xenopus* oocyte expression system is instructive but also must be interpreted with a degree of caution (Sullivan *et al.*, 1994; Sucher *et al.*, 1996). We do not yet fully understand how to form recombinant NMDARs that exactly mimic native receptors, and therefore conclusions based on site-directed mutagenesis studies of cysteine residues must be viewed with tempered enthusiasm. In fact, in the course of performing polymerase chain reaction (PCR) studies based on primers containing the cysteines known to be unique to NMDAR subunits, our group discovered a new NMDAR subunit (originally termed NMDAR-L or χ -1, but more recently named NR3A) (Ciabarra *et al.*, 1995; Sucher *et al.*, 1995; Das *et al.*, 1998). Additional unidentified NMDAR subunits probably remain to be identified. Thus, it is not yet possible to understand definitively the native NMDAR responses on the basis of recombinant subunits.

This statement notwithstanding, our data show that the cysteines at position 744 and 798 of the NR1 subunit are not only important to redox reactions in general, but also have

some (albeit minor) influence on the effect of NO and Zn^{2+} on the NMDAR; however, this can only be seen after chemical reduction of the receptor with DTT because of disulfide bond formation at this site. Structural evidence from crystallography experiments for disulfide formation between these cysteines has come from two cysteine residues on GluR2, which are homologous to Cys-744 and Cys-798 of NR1 and which were shown to form a disulfide bond (Armstrong *et al.*, 1998). Aizenman *et al.*, (1998) did not chemically reduce the NMDAR and thus failed to see the effect of S-nitrosylation at cysteine residues 744 and 798 of NR1. In an extensive series of experiments using site-directed mutagenesis of all cysteines on the known NMDAR subunits, we found that additional cysteine residues on the NR2A subunit contribute in a more important manner to the NO effect than Cys-744 and Cys-798 of NR1, indicating that the NMDAR is polynitrosylated to modulate its physiological function in a manner resembling the ryanodine receptor (Xu *et al.*, 1998). In brief, our results show two things. First, specific NMDAR subunit combinations manifest larger NO-induced decreases in activity than other receptor subunit combinations (e.g., a greater effect of NO is observed for NR1/NR2A than NR1/NR2B receptors) (Omerovic *et al.*, 1995; Sucher *et al.*, 1996). Second, seven cysteine residues on NR1 and NR2A mediate the effects of NO, Zn^{2+} , or redox agents on the NMDAR; six of these cysteine residues work in pairs, that is, apparently forming three disulfide bonds after exposure to oxidizing agents or, in the case of four of these cysteine residues, after reaction with NO^+ donors. One additional cysteine residue appears to be S-nitrosylated only and apparently does not form a disulfide. The effects of NO group transfer would be expected to be either relatively long lasting (in the case of disulfide formation) or more transient (in the case of reaction with a single thiol), and indeed both such effects have been observed on primary neurons. Although it appears that the NO effects are predominantly due to reaction with the single cysteine sulfhydryl on the NR2A subunit, the four other cysteine residues also contribute somewhat by reacting with NO^+ , but only if they are in the reduced state (Choi *et al.*, 2000). In contrast, the voltage-independent effects of Zn^{2+} on NR1/NR2A receptors are influenced by all of the aforementioned six cysteine residues that act in pairs and whose redox status can be modulated by DTT and DTNB.

By site-directed mutagenesis we found that a critical cysteine residue (Cys-399) on the NR2A subunit reacts under physiological (nonreducing) conditions by S-nitrosylation (transfer of NO^+) to underlie the major component of NO modulation of NMDAR activity. In cell systems expressing NMDARs with mutant NR2A subunits in which this single cysteine has been replaced by an alanine, the effect of endogenous NO is lost. Thus endogenous S-nitrosylation can serve as a regulatory mechanism for ion channel activity.

Inspection of NR1 and NR2 subunits revealed that an additional four cysteine residues resembled the consensus motif for S-nitrosylation (see below). In addition to NR2A Cys-399, only Cys-744 and Cys-798 in the M3–M4 extracellular linker of NR1 (as mentioned above), and Cys-87 and

Cys-320 of the extracellular N terminus of NR2A fit the consensus motif. Therefore, we also mutated these cysteines to alanines, yielding the heteromeric receptor NR1(C744A, C798A)/NR2A(C87A, C320A, C399A). The crystal structure of the GluR2 ligand-binding domain reveals a disulfide bond between cysteine residues homologous to NR1 C744 and C798, and this may also be true for NR2A C87 and C320 (Armstrong *et al.*, 1998). In the form of disulfide, these additional cysteine residues would not possess free thiol groups, and would therefore not be expected to react with NO. Indeed, under physiological conditions, we could not detect a statistically significant difference in SNOC-induced inhibition of NMDA-evoked currents between NR1/NR2A (C399A) and NR1(C744A, C798A)/NR2A(C87A, C320A, C399A) receptors. However, if we pretreated NR1/NR2A (C399A) with DTT to reduce the disulfide bonds to free thiol groups, we then observed an additional small but statistically significant inhibition by NO donors ($11 \pm 4\%$, $n = 10$; $p < 0.05$ by ANOVA). Reminiscent of polynitrosylation of the ryanodine receptor, these results suggest that multiple cysteine residues may react with NO, depending on the redox state of the NMDAR, and this may account for prior divergent findings in different laboratories (Lipton *et al.*, 1998; Aizenman and Potthoff, 1999). Our results indicate, however, that even though NR1(C744, C798) and NR2A(C87, C320) can possibly interact with NO, the effect is quite small and occurs under nonphysiological, chemical reducing conditions. Hence, the main effect of both exogenous and endogenous NO on NMDAR responses occurs at NR2A(C399) under physiological conditions, that is, in the absence of prior exposure to reducing or oxidizing agents (Choi *et al.*, 1999).

Other effects of NO on the NMDAR are of course not ruled out by these findings. It is also true that the effects of Zn^{2+} on the NMDAR and that of redox agents can be confused because some reducing agents (such as DTT) bind Zn^{2+} , because EDTA chelates Zn^{2+} , and because Zn^{2+} may also be coordinated, at least in part, by cysteine residues. It had been proposed by Bockaert and co-workers that NO can react with a Zn^{2+} site of the NMDAR (Fagni *et al.*, 1995). However, we can now explain all of these previous findings with our more recent work showing that the effect of Zn^{2+} can be influenced by the redox state of the six cysteine residues on the NMDAR that are discussed above, four of which can also react with NO^+ . Hence, it appears that at least some sites of NO^+ and Zn^{2+} action may share common cysteine residues.

Nitroglycerin Decreases NMDAR Activity and Attenuates Neurotoxicity

On the basis of the above findings, the ideal NO group donor drug would be one that reacts readily with critical thiol groups of the NMDAR to inhibit excessive Ca^{2+} influx but does not produce NO^\bullet to react with O_2^- , so it will not lead to the formation of peroxynitrite (ONOO^-). We therefore studied nitroglycerin (NTG) as an exemplary compound.

Specifically, alkyl nitrates such as NTG do not directly liberate nitric oxide ($\text{NO}\cdot$) to any significant extent; rather, they react readily with thiol groups to form derivative thionitrites (RS-NO) or thionitrates (RS-NO_2) (together, these are represented as RS-NO_x , with $x = 1$ or 2 ; Fig. 1) (Lei *et al.*, 1992; Lipton *et al.*, 1993). Using whole-cell recording with patch clamp electrodes and digital calcium imaging with fura-2 on primary cerebrocortical neurons, we found that NTG inhibited NMDA-evoked currents and Ca^{2+} influx (Lei *et al.*, 1992; Lipton *et al.*, 1993). Strong evidence that this effect of NTG is mediated by its reactions with thiol in the previously illustrated manner came from a series of chemical experiments. These studies showed that under our conditions specific alkylation of thiol groups with NEM completely abrogated the inhibitory effect of NTG on subsequent NMDA-evoked responses (Lei *et al.*, 1992). Moreover, more recent work on recombinant NMDAR subunits has revealed that specific thiol-reactive agents, such as 2-aminoethylmethanethiosulfonate (MTSEA) and 2-(trimethylammonium)ethyl methanethiosulfonate (MTSET), can completely block the effect of NO on NMDAR activity, again consistent with the

fact that NO/thiol group reactions account for this effect (Choi *et al.*, 2000; Kim *et al.*, 1999).

The finding that NTG could inhibit NMDA-evoked responses was consistent with the demonstration that similar concentrations of NTG could also significantly ameliorate NMDA-induced neuronal killing in cerebrocortical cultures (Lei *et al.*, 1992; Lipton *et al.*, 1993). Additional *in vivo* data show that high doses of nitroglycerin are neuroprotective in rat models of focal ischemia under conditions of constant systemic blood pressure and modestly increased cerebral blood flow in the penumbra (Lipton and Wang, 1996). These parameters are held stable either by inducing tolerance to the systemic effects of NTG through chronic transdermal application (Sathi *et al.*, 1993), or by intravenous infusion of a pressor agent concurrently with nitroglycerin (Lipton and Wang, 1996). Although difficult to prove *in vivo*, it appears likely that the decrease in stroke size observed after treatment with NTG is at least in part due to its effect on decreasing NMDAR activity, although several other beneficial actions also occur (see below) (Lipton and Wang, 1996).

S-Nitrosylation of Caspases

As introduced earlier, another example of beneficial NTG and S-nitrosylation reactions that can prevent neuronal cell death involves caspases. Caspases are members of the interleukin-1 β -converting enzyme (ICE)–CED-3 protease family of enzymes that play a crucial role in mammalian apoptosis either during development or due to growth factor deprivation. Additionally, caspases have been implicated in the pathway to neuronal apoptosis from mild excitotoxic insults (Tenneti *et al.*, 1997, 1998). More intense excitotoxic injuries evoke rapid and irreversible energy compromise, leading to the failure of ionic homeostasis with consequent swelling and lysis (Ankarcrona *et al.*, 1995; Bonfoco *et al.*, 1995); this form of cell death represents necrosis and is not dependent on caspases (Tenneti *et al.*, 1998). One new regulatory pathway of caspase activity involves S-nitrosylation. In a recent development in the apoptosis field, in primary cerebrocortical neurons (Tenneti *et al.*, 1997), and in other cell types (Dimmeler *et al.*, 1997; Melino *et al.*, 1997; Ogura *et al.*, 1997), caspase activity has been found to be decreased by S-nitrosylation or transfer of an NO^+ -like group to a critical cysteine sulphydryl that is located in the active site in all caspase enzymes. This finding has important implications for the regulation of apoptosis by the NO group: under specific redox conditions that favor nitrosylation of caspases, apoptosis can be attenuated by decreasing caspase activity, whereas conditions favoring the generation of $\text{NO}\cdot$ will lead, via reaction with O_2^- , to the production of peroxynitrite and consequent cell death (either apoptotic or necrotic depending on the intensity of the insult).

A Variety of Targets for S-Nitrosylation

After NMDAR activity was shown to be regulated by NO-related species, similar data were presented for the

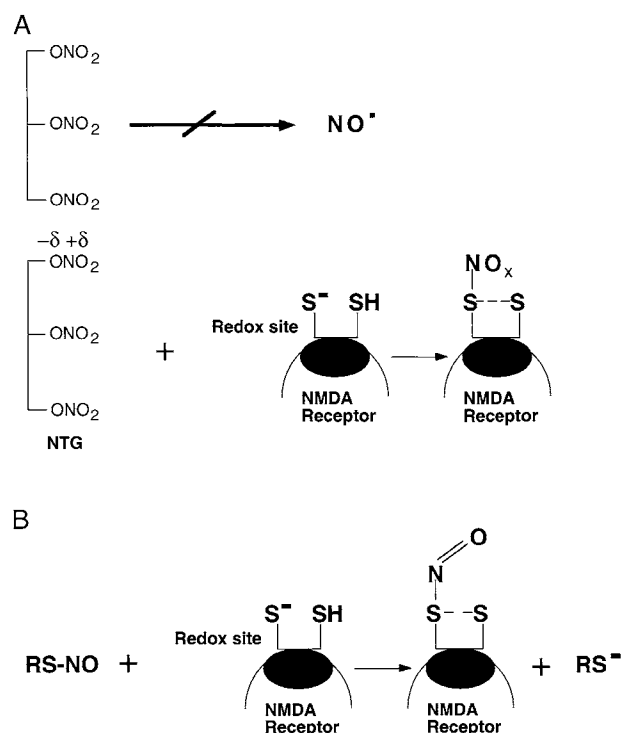

Figure 1 Schematic model of S-nitrosylation of the NMDA receptor. Chemical mechanism of action of nitroglycerin (NTG) with thiol groups (A) and of S-nitrosocysteine (an RS-NO) with thiol groups (B) on the NMDA receptor. NTG itself does not directly generate nitric oxide ($\text{NO}\cdot$). Instead, NTG transfers NO_x^+ (where $x = 1$ or 2) to critical thiol groups of NMDA receptor cysteine residues (in some cases this may facilitate disulfide bond formation, indicated by a dashed line). In the case of RS-NO , NO^+ is transferred to thiol. This reaction results in decreased activity of NMDA receptor-operated channels. [Reproduced with permission from Lipton, S. A. (1999). Neuronal protection and destruction by NO. *Cell Death Differ.* 6, 943–951.]

Ca^{2+} -activated K^{+} channel of cardiac muscle (Bolotina *et al.*, 1994). In this case, donors of NO^{+} equivalents were shown to activate the channel, and, similar to findings at the NMDAR in our laboratory, NEM blocked the effect by irreversibly alkylating thiol groups. Along similar lines, several other ion channels, enzymes, G proteins, transcription factors, and other proteins are either upregulated or downregulated by similar mechanisms of S-nitrosylation or donation of NO^{+} equivalents to regulatory sulfhydryl centers (Stamler *et al.*, 1997). The list will undoubtedly grow, just as phosphorylation, myristoylation, and palmitoylation have become recognized as important biochemical processes for regulatory function. Interestingly, palmitoylation may be aimed at similar critical thiol group targets, resulting in thioester bond formation. In fact, on some proteins such as SNAP-25 it is possible that S-nitrosylation and palmitoylation may compete for the same sulfhydryl group, possibly with different physiological outcomes (Hess *et al.*, 1993).

In contrast to better known intracellular regulatory processes such as phosphorylation, S-nitrosylation of critical cysteine residues can occur extracellularly, intracellularly, or possibly even within the putative membrane-spanning region of a protein. From this point of view, S-nitrosylation may offer additional versatility in the location of control that can be exerted compared to phosphorylation and other better known posttranslational forms of modification (Choi *et al.*, 2000).

Proposed Consensus Motif for S-Nitrosylation

The primary amino acid sequence of functionally important sites for posttranslational modification of proteins are distinguished by the occurrence of certain patterns or motifs. In many cases such motifs constitute only a very minor part of the entire protein primary sequence. Thus, small patterns often are not detected by overall alignment of protein sequences that are only distantly or not at all related. Such motifs, however, can be identified by the occurrence of a particular cluster of residue types in the primary sequence. A collection of such sequence fingerprints has been developed for PROSITE, a data base of biologically significant sites and patterns that can be used to identify families of functionally related proteins or sites for posttranslational modification. Examples of such motifs are the consensus sequence patterns required for glycosylation or phosphorylation.

In an attempt to define a possible consensus motif that might be required or at least be facilitatory for S-nitrosylation, in collaboration with the laboratories of Nikolaus Sucher and Jonathan Stamler, we initially examined the putative target sites for redox modulation of NMDARs. Most importantly, cysteine residues in motifs similar to that described later for the NMDAR have been shown by various chemical criteria to be nitrosylated on proteins such as hemoglobin, p21^{ras}, cyclooxygenase, and others (Stamler *et al.*, 1997). As discussed earlier, two cysteines (abbreviated C in the single letter amino acid code) in the NR1 subunit have been found by site-directed mutagenesis to be necessary for the persist-

ent component of redox modulation of that receptor (Sullivan *et al.*, 1994), and in the reduced state they can be S-nitrosylated (Choi *et al.*, 2000). Unexpectedly, however, these cysteines, C744 and C798, appear to be conserved in all ionotropic glutamate receptors when the sequences are aligned by overall similarity (Moriyoshi *et al.*, 1991; Sucher *et al.*, 1995). Nonetheless, among the ionotropic glutamate receptors, only NMDARs are exquisitely sensitive to redox modulation and NO effects (Aizenman *et al.*, 1989; Lei *et al.*, 1992). Inspection of the immediate amino acid neighbors of these cysteines revealed that the NR1 cysteines are distinguished from the cysteines conserved in the other ionotropic glutamate receptors in that they are preceded at position -2 by a polar amino acid (G, S, T, C, Y, N, Q), an acidic (D, E) or basic (K, R, H) amino acid at position -1, and an acidic amino acid at position +1. On the basis of this observation, we constructed the degenerate amino acid pattern designated (G,S,T,C,Y,N,Q)(K,R,H,D,E)C(D,E) in standard single letter amino acid code and used it in a search of the Protein Identification Resource (PIR) and Swiss Protein (SW) databases with the program Find patterns of the GCG software package (Program Manual for the Wisconsin Package, Version 8, September 1994, Genetics Computer Group, 575 Science Drive, Madison, Wisconsin 53711). In the PIR database (Release 44.0; March 1995), 3878 sequences out of 77,573 contained this pattern at least once, and in the SW database (Release 31.0; March 1995), 2383 out of 43,470 sequences contained this pattern. Viral, bacterial, plant, and animal sequences contained this motif.

Among candidates for regulation by S-nitrosylation that were identified by the database search were ion channels (NMDAR, voltage-sensitive Na^{+} channel, cyclic nucleotide-gated channel), transporters (Ca^{2+} -ATPase, K-transporter), receptors (inositol trisphosphate receptor, nerve growth factor receptor), enzymes (oxidoreductases, dehydrogenases, adenylate and guanylate cyclases, proteases, DNA topoisomerases, DNA and RNA polymerases, kinases, phosphatases), transcription factors (helix-loop-helix proteins, NF- κ B, zinc finger proteins), small GTP-binding proteins (rab, ras, sas, ypt), cell adhesion molecules (integrins, neural cell adhesion molecule), cell adhesion substrates (laminin, collagen), cyclins, and coagulation factors (IXa, Xa, XIII).

In fact, 20 of 27 proteins that had been listed in a review (Stamler, 1994) as bioregulatory targets of nitrosylation contain the full motif. The presence of the putative nitrosylation motif in guanylate cyclase suggests that the NO group may regulate the functional activity of guanylate cyclase by S-nitrosylation in addition to the interaction with the heme group of this enzyme. It is possible, however, that S-nitrosylation might occur at sites other than the proposed motif, or that the motif may only be evident in the tertiary rather than the primary structure of some proteins (this appears to be true for the caspases, for example). Moreover, it appears that a certain subset of the motif (basic or acidic amino acid residue-cysteine residue-acidic residue) may bear the highest statistical correlation to the propensity for nitrosylation (Stamler *et al.*, 1997). Although the proposed motif was de-

fined post hoc on the basis of our results with redox modulation of the NMDAR, it should allow us to identify additional possible target proteins for S-nitrosylation. Most importantly, this motif predicts a target sequence that can be subjected to site-directed mutagenesis in order to experimentally verify its importance for S-nitrosylation. Finally, for the NMDAR, site-directed mutagenesis has shown that the major determinant of S-nitrosylation occurs at the cysteine residue at position 399 of the NR2A subunit, which fits the proposed consensus motif for nitrosylation. Reversed-phase HPLC evidence has demonstrated, on a peptide containing the N-terminal region of this NMDAR subunit, that S-nitrosothiol formation indeed occurs by chemical criteria (Choi *et al.*, 2000).

Proposed Nitroxyl Reactions with Cysteine Thiol

It has been proposed that NO^- can be generated in two forms, NOH or HNO, both of which may exist in the triplet or singlet states (Bonner and Stedman, 1996; Wink and Feehlich, 1996). For example, in the singlet state, two antibonding electrons occupy a single outer π^* (pi antibonding molecular orbital), with spins opposed. In the triplet state the two π^* antibonding orbitals each contain an electron with spins aligned (with a z component of electron spin of +1, 0, or -1; hence, the designation "triplet state"). In the singlet state, we have found evidence that NO^-/HNO (pK_a 4.7) can react most likely directly with critical thiols of the NMDAR to yield either an R-SNH-OH derivative or possibly a disulfide, in which case hydroxylamine (NH_2OH) is also formed (Fig. 2A) (Doyle *et al.*, 1988; Arnelle and Stamler, 1995). Triplet NO^- does not react directly with thiol groups but can react with O_2 , forming peroxynitrite (Stamler *et al.*, 1992b; Arnelle and Stamler, 1995; Butler *et al.*, 1995), which does react with thiol (Radi *et al.*, 1991). At low concentrations peroxynitrite decreases NMDA receptor activity by oxidizing critical thiol groups (Kim *et al.*, 1996), whereas it is neurodestructive at higher concentrations (Beckman *et al.*, 1990; Dawson *et al.*, 1993; Lipton *et al.*, 1993). We therefore speculate that triplet NO^- is acting here via formation of low concentrations of ONOO^- to downregulate NMDA receptor activity (Fig. 2B). These reactions decrease NMDAR activity (Lipton *et al.*, 1993; Lipton and Stamler, 1994). The chemistry of S-nitrosylation of the NMDAR (Choi *et al.*, 2000) and nitroxyl reactions with the NMDAR has been detailed (Kim *et al.*, 1999).

Conclusions

Possible chemical reactions of the NO group are dictated by its redox state. In the case of NO^+ equivalents, this mechanism appears to involve S-nitrosylation and possibly further oxidation of critical thiols to disulfide bonds on the NMDAR to decrease channel activity; a cysteine residue, known to be present in the active site of all known caspase enzymes, can also be S-nitrosylated, resulting in inhibition of enzyme ac-

Figure 2 Proposed mechanism for the action of NO^- (nitroxyl anion). It has been proposed that NO^- can be generated in two forms, NOH or HNO, both of which may exist in the triplet or singlet states (Gallup, 1975). For example, in the singlet state, two antibonding electrons occupy a single outer π^* (pi antibonding molecular orbital), with spins opposed. In the triplet state the two π^* antibonding orbitals each contain an electron with spins aligned (with a z component of electron spin of +1, 0, or -1). (A) In the singlet state, NO^-/HNO (pK_a 4.7) can react with critical thiols of the NMDA receptor to yield an R-SNH-OH derivative (A1) or disulfide (A2), in which case hydroxylamine (NH_2OH) is also formed (Arnelle and Stamler, 1995). These reactions would downregulate NMDA receptor activity (Doyle *et al.*, 1988; Lipton *et al.*, 1993; Sullivan *et al.*, 1994). To confirm this type of reaction scheme, we have shown that hydroxylamine forms when an NO^- generating drug reacts with vicinal thiols. Thus, reactions of singlet NO^- are likely to be neuroprotective. (B) Triplet NO^- , rather than reacting directly with thiol, tends to react with molecular oxygen to form peroxynitrite (ONOO^-) (Hughes and Nicklin, 1971; Bonner and Stedman, 1996), which can also oxidize thiols to disulfide (B1) (Radi *et al.*, 1991); this reaction can be reversed with DTT. Alternatively, ONOO^- can oxidize thiol to produce an -OH modification of sulfur (a sulfenic acid or R-SOH, as shown in B2), which is also reversible with DTT (Becker *et al.*, 1998; Stamler and Hausladen, 1998). Indeed, we have demonstrated that at low concentrations peroxynitrite downregulates NMDA receptor activity, apparently reacting at a redox modulatory site(s) on the receptor, as DTT can reverse this effect (Kim *et al.*, 1996). Such effects of triplet NO^-/O_2 , although supportive of the molecular mechanism entertained here and theoretically neuroprotective, are likely to be more tenuous *in vivo*, as peroxynitrite is a powerful oxidant that has been shown to account for NO-related neurotoxicity (Beckman *et al.*, 1990; Dawson *et al.*, 1993; Lipton *et al.*, 1993). [Adapted with permission from Kim *et al.*, (1999). *Neuron* **24**, 461–469.]

tivity. These effects of S-nitrosylation, and undoubtedly others, can lead to neuroprotection by “NO donors” such as NTG, which favor S-nitrosylation or related reactions. In contrast, NO[•] (with one more electron than NO⁺) kinetically prefers to react with O₂^{•-} to yield peroxynitrite (ONOO⁻), which is neurodestructive. Finally, nitroxyl anion (NO⁻) has one additional electron compared to NO[•] and can exist in at least two different chemical states (singlet and triplet) with distinct reactivities that can directly or indirectly support reactions with thiol groups on the NMDAR, among other proteins.

It is becoming increasingly evident that in addition to those of NMDARs and caspase enzymes, the biological activities of many other proteins containing critical cysteine residues can be regulated by S-nitrosylation and other redox reactions, in a sense similar to the type of control exerted by phosphorylation (Lipton *et al.*, 1993). This type of chemical reaction may represent a new and ubiquitous pathway for the molecular control of protein function by potentially reactive sulfhydryl centers.

Acknowledgments

This review is based on work performed in a close collaboration between the laboratories of Stuart Lipton, then at Harvard Medical School, Jonathan Stamler at Duke Medical Center, Pierluigi Nicotera at the University of Konstanz (Germany), and Nikolaus Sucher at the Hong Kong University of Science and Technology. We are grateful to the many members of our laboratories who contributed. The work was presented at several recent meetings, and this is reflected in the proceedings of these meetings and other reviews. However, the present chapter has been updated to reflect more current work.

THIS CHAPTER DISCUSSES THE PRACTICAL ASPECTS OF MEASURING NITRIC OXIDE (NO) AND NITRIC OXIDE SYNTHASE (NOS) IN BIOLOGICAL SPECIMENS FROM ANIMALS AND HUMANS. IT DEALS WITH THE ISSUES OF EXPERIMENTAL PARADIGMS FOR INDUCING NO AND THE REASONS FOR THE DIFFERENCES IN THE ABILITY TO INDUCE NO IN RODENT AND HUMAN CELLS, WITH AN EMPHASIS ON THE IMPLICATIONS OF USING ANIMAL MODELS FOR DERIVING USEFUL INFORMATION ABOUT TREATING HUMAN DISEASE. A SECOND ASPECT OF THE CHAPTER REVIEWS THE ROLE OF NO IN AN ANIMAL MODEL FOR MULTIPLE SCLEROSIS (MS), EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS (EAE), AS WELL AS EVIDENCE FOR NO PRODUCTION IN MS. GENERAL CONCEPTS REGARDING THE REGULATION OF NO OF AND BY THE IMMUNE RESPONSE ARE DISCUSSED WITH SPECULATIONS REGARDING THE INTERACTIONS OF THESE MOLECULES IN ALTERING THE DISEASE COURSE IN MS PATIENTS. THE CONCLUSION OF THIS CHAPTER IS THAT NO REGULATES GENE TRANSCRIPTION AS WELL AS THE INTEGRITY, STRUCTURE, AND FUNCTION OF PROTEINS AND MOLECULES AND, IN THE CONTEXT OF AUTOIMMUNE DISEASE, MAY ACT AS A PRO- OR ANTI-INFLAMMATORY MOLECULE.

Introduction

Multiple sclerosis (MS) is a demyelinating disease of the central nervous system (CNS) thought to be of immune origin. Activated T cells and immunoglobulin-producing B cells converge in the white matter where an inflammatory milieu is created, initiating the influx of macrophages from the blood and the activation of the endogenous macrophages called microglia. Although the major amount of supporting data that free radicals contribute to the reactive gliosis, oligodendrocyte cell death, and demyelination is derived from the animal model for MS, experimental autoimmune encephalomyelitis (EAE) (see below), there is some evidence from

patient material as well. Free radicals or their metabolites as well as lipid peroxidation products are elevated in plasma and cerebrospinal fluid (CSF) of MS patients (Glabinski *et al.*, 1993; Hunter *et al.*, 1985). Spectroscopic changes have demonstrated lipid and protein oxidation in brain samples containing MS lesions (Levine and Warren, 1998). Antioxidants, thought to provide protection against oxidative stress, are elevated in MS sera (Gutowski *et al.*, 1998). Myeloperoxidase is present in MS brain macrophages/microglia (Nagra *et al.*, 1997), thereby offering an additional mechanism for free radical generation in the CNS. With regard to the etiology of MS, it has been postulated both that free radicals are the consequence of immune activation of inflammatory

cells as well as that infections or trauma initiate free radical formation which then activates T cells and sets off an autoimmune cascade (Cooper, 1997).

This chapter will deal with the issues of production and regulation of nitric oxide (NO) *in vivo* and *in vitro* in both MS tissues and cells. This discussion and the analysis of the role of NO in the EAE model will be presented in the format of general principles, allowing a better understanding of how nitric oxide may function in the presence or absence of free radicals of oxygen. Furthermore, the concept that NO may function in both inflammation and repair, thereby acting in both a proinflammatory and anti-inflammatory capacity, will be considered.

Methods Used for Detection of iNOS/NO in CNS Tissues

Inducible nitric oxide synthase (iNOS or type II NOS) has been identified as the isoform of interest in the inflammatory lesions in MS and EAE. Its presence and function have been assessed in tissues such as brain and spinal cord, sera, and cerebrospinal fluid, as well as in *ex vivo* leukocytes derived from patients with MS or animals with EAE, using biochemical, immunohistochemical, and molecular techniques. Identification of NO-triggered events or "footprints" is also useful to substantiate the presence of functional iNOS enzyme and NO production. iNOS generates higher levels of NO than type I or III NOS isoforms: *ex vivo* or *in vitro* 10⁶ cells can produce nanomoles to micromoles of NO in a period of hours to days, thereby allowing measurement with the colorimetric assay for nitrite (NO₂⁻) and nitrate (NO₃⁻). Nevertheless, there are some major differences in the stimuli required and kinetics of NO production when comparing human and rodent cells, which need to be carefully considered when interpreting negative results (reviewed in Parkinson *et al.*, 1997; Mitrovic *et al.*, 1996). These will be discussed in the context of comparisons of MS and EAE.

Determination of NO₂⁻ Plus NO₃⁻ and Citrulline Levels

The fluorometric assay for nitrite (NO₂⁻) plus nitrate (NO₃⁻) and the radiochemical assay for L-citrulline provide greater sensitivity at lower arginine concentrations than other NOS enzyme assays and are suitable end-point assays for studying enzyme kinetics. Such assays have been used in assessing NO₂⁻/NO₃⁻ levels in CSF and sera and in assessing NO produced by MS leukocytes *ex vivo* with or without stimulation and by human and rodent glia stimulated by cytokines in *in vitro* cultures. The radiochemical assay for citrulline can be performed using either [³H]- or [¹⁴C]arginine, with separation of arginine from citrulline on ion-exchange resins at low pH. This assay can be used for stoichiometric and kinetic analyses of NOS activity when NOS activity is low in samples; it is superior in sensitivity to the fluorimetric

analysis and can be adapted to high-throughput assays using spectrophotometric analysis on plate readers. In aqueous or biological solutions, such as culture supernatants, sera, and CSFs, NO oxidizes rapidly to equilibrium mixtures to NO₂⁻ plus NO₃⁻. Since the ratio between these two species varies considerably in biological samples, it is advisable to measure the sum of both metabolites to avoid underestimation of NO. This is especially true in human samples, where NO₂⁻ is rapidly oxidized to NO₃⁻, in comparison to what has been found in rodent samples (Ikeda *et al.*, 1995). Colorimetric determination, based on diazotization of sulfanilic acid and (1-naphthyl)ethylenediamine (Griess reagent) has been widely used. For ease in assessment, enzymatic conversion of NO₃⁻ to NO₂⁻ by nitrate reductase, followed by fluorimetric or colorimetric NO₂⁻ assay, is preferred by many investigators. Nevertheless, a quantitative conversion of NO₃⁻ to NO₂⁻ to NO can be achieved using boiling vanadium(III) under acidic conditions, thereby yielding measurement of total NO (NO_x) which is, in some samples, more or less equivalent to NO₂⁻ levels determined by the Griess reagent plus nitrate reductase (Ding *et al.*, 1997; Ding and Merrill, 1997).

In Situ Detection of NOS Protein, mRNA, and Activity

Several histochemical and molecular techniques have been used to identify the presence, anatomical location, cellular distribution, and function of iNOS in MS brain and spinal cord (Parkinson *et al.*, 1997; Mitrovic *et al.*, 1996). Isoform-specific anti-NOS antibodies have been developed and are now commercially available from Transduction Laboratories (Lexington, KY) and Santa Cruz Biotech (Santa Cruz, CA), among others; use of such polyclonal and monoclonal antibodies to human iNOS has demonstrated the enzyme in human tissues including brain, lung, *ex vivo* leukocytes, and *in vitro* cultured human glia. iNOS protein can be induced in human glia within a few hours of stimulation with cytokines *in vitro* (Ding *et al.*, 1997; Lee *et al.*, 1993). Important considerations when attempting to stain human tissues or cultured cells with these reagents are (1) the specificity to a NOS domain is distinct from the C-terminal flavoprotein reductase domain, which has considerable homology with other flavoprotein reductases, leading to non-specific staining; (2) species cross-reactivity for iNOS reagents is lower than that for the two constitutive isoforms; (3) some reagents identifying the isoform-specific N-terminal region of human iNOS may work on cultured cells or on Western blots but not on tissue sections because of inaccessible epitopes (rendered so by fixation), natural endogenous epitope masking, or low antibody affinity (Parkinson *et al.*, 1997).

Northern blot analysis or reverse transcriptase-polymerase chain reaction (RT-PCR) for iNOS mRNA in extracted samples, and *in situ* hybridization or *in situ* RT-PCR (RT-IS-PCR) for iNOS mRNA coupled to immunohistochemical identification of specific cells or iNOS protein-containing

cells, have been used in MS tissues (Lee *et al.*, 1993; Bagasra *et al.*, 1995; Ding and Merrill, 1997; DeGroot *et al.*, 1997). mRNA for iNOS is not seen in uninduced human glia *in vitro* but can be seen within 2 to 8 hours after cytokine induction (Lee *et al.*, 1993; Ding *et al.*, 1997). Since enzyme activity occurs and NO is only formed when NOS is conformationally in a head to head dimer, the presence of neither mRNA nor protein means that functional iNOS enzyme exists in cells or tissues (Ding *et al.*, 1997; Ding and Merrill, 1997). As in the case of other oxidoreductases, NOS has intrinsic diaphorase activity and can transfer electrons from NADPH to alternative electron acceptors such as ferricyanide, cytochrome *c*, and tetrazolium salts. The reaction of NOS with nitroblue tetrazolium in the presence of NADPH is the basis of the NADPH diaphorase (NADPHd) staining in tissues for identification of the presence of NOS. There is some discrepancy as to which cell type produces iNOS in MS tissues when comparing the studies using NADPHd staining compared to iNOS staining (Lee *et al.*, 1993; Brosnan *et al.*, 1994; Bö *et al.*, 1995; Bagasra *et al.*, 1995; DeGroot *et al.*, 1997; Ding and Merrill, 1997). Because not all NADPHds are iNOS and not all NOS functions as NADPHd, and since fixation may greatly influence the NADPHd detection, the use of specific antibodies with double staining for cell subtypes is a more reliable technique for identifying iNOS-positive cells in tissues (Mitrovic *et al.*, 1996; Parkinson *et al.*, 1997).

Indirect Detection of NO Formation by Assessment of "Footprints"

When assays for detection of functional enzyme or NO and its metabolites are not easy or possible, as in brain and spinal cord tissue, an indirect assessment must be made through examining the chemical reactants induced or modified by NO. Additionally, the disparity in the kinetics of the presence of iNOS enzyme, which occurs days before the appearance of NO in culture supernatants or the extractability of L-citrulline from cell lysates of human cells (glia or macrophages), suggests that confirmatory assays for the production of NO are desirable (Ding and Merrill, 1997). NO or donors of NO can stimulate the activity of soluble guanylate cyclase, which then increases intracellular cGMP; thus, a cGMP radioimmunoassay is an indirect method of determining NO production. However, it is crucial to remember that this is not quantitative, nor is it specific for NO. Nevertheless, this assay can be used to show the presence of NO in biological systems, and it has been used to confirm studies demonstrating the signaling functions of NO in neurons. NO as a neurotransmitter can be mimicked by addition of soluble guanylate cyclase activators and upregulated by cGMP phosphodiesterase inhibitors (Ding *et al.*, 1997; Ding and Merrill, 1997).

NO reacts with superoxide anion (O_2^-) to form the powerful oxidizing agent peroxynitrite ($ONOO^-$). $ONOO^-$ can nitrate phenolic rings, forming 3-nitrotyrosine (NT) (Beckman *et al.*, 1994). Antibodies to NT have been developed

and successfully used in many inflammatory tissues including MS and EAE brain and spinal cord to identify nitrated tyrosines on proteins (Bagasra *et al.*, 1995; DeGroot *et al.*, 1997; van der Veen *et al.*, 1997; Hooper *et al.*, 1997; Merrill *et al.*, 1998). This is of significance given that NT staining (a) is not seen in normal tissues, (b) colocalizes with areas of active lesion formation in MS and EAE where iNOS staining is also seen, and (c) will remain as evidence of previous foci of inflammation long after iNOS is downregulated as in burnt out lesions in MS brain tissue (Merrill *et al.*, 1998). Furthermore, a delayed kinetics of cGMP production and nitrotyrosine staining in cultured human glial cells has been shown to parallel the NO and L-citrulline detection, thereby validating the use of NO "footprints" as indicators of functional enzyme in a given biological system (Ding *et al.*, 1997; Ding and Merrill, 1997).

Evidence for iNOS/NO Production in MS

Brain and Spinal Cord Tissue

Two separate reports published from the same laboratory have demonstrated in MS tissue the colocalization of the purported macrophage marker *Ricinus communis* agglutinin (RCA-1) lectin and iNOS mRNA, as detected by reverse transcriptase-*in situ* PCR (Bagasra *et al.*, 1995; Hooper *et al.*, 1997). There have been no published studies using double immunostaining with a cell-specific marker and an iNOS-specific antibody in MS or EAE tissue. Indeed, no studies have colocalized NT to specifically labeled cells in MS lesions (Brosnan *et al.*, 1994; Bagasra *et al.*, 1995; Bö *et al.*, 1995; DeGroot *et al.*, 1997). There is some disagreement in the published reports on MS tissues as to whether astrocytes, microglia, or indeed both cell types make iNOS. Two studies using NADPHd as an indicator of iNOS found that it colocalized with astrocytes only (Brosnan *et al.*, 1994; Bö *et al.*, 1995). Three other studies found no iNOS staining in astrocytes, but did find NADPHd staining in CD68-positive cells (DeGroot *et al.*, 1997) or iNOS mRNA in RCA-1-positive cells (Bagasra *et al.*, 1995; Hooper *et al.*, 1997). Since NADPHd is not iNOS specific and does not directly correlate with the NOS activity of any of the three isoforms *in vivo* in tissues (Tracey *et al.*, 1993; Gonzalez-Hernandez *et al.*, 1996), we produced a specific antibody to a unique sequence in the amino terminus of human iNOS to assess the presence of this isoform in cells *in vitro* (Ding and Merrill, 1997) and *in vivo*. It is clear that several cell types might be able to produce iNOS and NO, and because the production of NO is elevated in MS patients (Boullerne *et al.*, 1995; Johnson *et al.*, 1995), it is important to quantitate both iNOS and NT staining in specific cell types in tissues from MS patients containing lesions at different stages of development. Data generated in this laboratory have shown that NO is produced by up to five distinct cell types in MS lesions: blood-borne macrophages, perivascular microglia, activated parenchymal microglia, gliotic astrocytes, and cells associ-

ated with endothelial cells at the blood–brain barrier (BBB) (possibly pericytes or Mato cells). The amount of iNOS and NT staining appears to correlate with the stage of the lesion (Merrill *et al.*, 1998).

Sera and Cerebrospinal Fluid

Analyses of CSF and sera from MS patients in several studies have demonstrated increased $\text{NO}_2^-/\text{NO}_3^-$ levels compared to noninflammatory neurological controls (Johnson *et al.*, 1995; Yamashita *et al.*, 1997; Giovanni *et al.*, 1997, 1998; Giovanni, 1998), although one study found no differences (Ikeda *et al.*, 1995), the reasons for which are not identifiable since all studies used the Griess reaction method. In the positive studies, the $\text{NO}_2^-/\text{NO}_3^-$ levels in the CSF were 10–20 μM and 40% above controls, whereas serum levels were 5–10 times the amount determined in CSF and 20% above controls. In the Ikeda study, where MS NO production was not elevated, $\text{NO}_2^-/\text{NO}_3^-$ levels were under 10 μM , suggesting the possibility of problems with sample preservation, assay inhibitors, or background (Ikeda *et al.*, 1995). One published study demonstrated a relationship of NO to relapses, whereas a second study found no relationship to disability (Yamashita *et al.*, 1997; Giovanni *et al.*, 1997). Other indicators that NO may be chronically upregulated in MS CNS have been reported; these include increased CSF neopterin, a precursor of iNOS cofactor tetrahydrobiopterin (Johnson *et al.*, 1995) and circulating antibodies to an immunogenic nitroso amino acid, *S*-nitrosocysteine (Boullerne *et al.*, 1995).

Blood Macrophages *ex Vivo*

Although it has been somewhat difficult *in vitro* to demonstrate that human blood-borne M Φ make iNOS/NO, after cross-linking of CD69, CD23, and the receptor for HIV-1/gp120, human M Φ can be activated to produce NO (De-Maria *et al.*, 1994; Bukrinsky *et al.*, 1995; Vouldoukis *et al.*, 1995). Additionally, human alveolar M Φ in lung tissue of individuals with a wide spectrum of acute and chronic inflammatory conditions have been shown to be iNOS positive *in vivo* (Kobzik *et al.*, 1993; Nicholson *et al.*, 1996), and/or to produce iNOS *ex vivo* (Nicholson *et al.*, 1996). López-Moratalla *et al.*, (1997) have shown that peripheral blood M Φ , freshly isolated from MS patients, but not controls, constitutively express iNOS and produce NO. In a second study, NO production by blood cells was associated with increased production of proinflammatory cytokines and, therefore, could be considered as a marker of mononuclear cell activation, and thus an indirect marker of disease activity in the peripheral blood of MS patients. Sarchielli *et al.* (1997) demonstrated that both basal NO and stimulated NO production by *ex vivo* peripheral blood mononuclear cells (PBMC) were significantly elevated in patients with active lesions as detected by MRI than those without active lesions. Patients without active disease produced NO levels that were no different from controls. During relapse, NO production by PBMCs was elevated over that in stable stages. NO levels

fell during recovery phase from relapses. NO production by PBMCs was positively correlated with their production of interleukin 1 β (IL-1 β), tumor necrosis factor α (TNF- α), and γ -interferon (IFN- γ) and negatively correlated with IL-10, and transforming growth factor β (TGF- β).

Other Neurodegenerative Diseases

Type II nitric oxide synthase has been identified in other neurodegenerative disease tissues. iNOS and NT staining have been seen in astrocytes in progressive supranuclear palsy, a nonhereditary neurodegenerative disorder involving neurofibrillary tangles and neuronal loss in the brain stem, basal ganglia, and cerebellum (Komori *et al.*, 1998). Oxidative stress and lipid peroxidation have been implicated in Alzheimer's disease (AD). Vodovotz *et al.* (1996) were the first to identify, by immunohistochemical techniques, iNOS in tangle-bearing neurons of AD brain tissue. Several studies have found iNOS in AIDS brains by PCR, although by the highly sensitive RT-IS-PCR, Bagasra *et al.* (1997) were not able to see the iNOS message. As in the MS cases, $\text{NO}_2^-/\text{NO}_3^-$ levels were high in sera and CSF of HIV-1-positive patients, and an albumin quotient indicated NO was being produced intrathecally (Giovanni *et al.*, 1998). NT staining in neurofibrillary tangles (NFT) as well as in neurons lacking NFTs has been seen in AD. Interestingly, no reaction was seen in extracellular NFTs, amyloid deposits, or dystrophic neurites of senile plaques. NT was undetectable in cerebral cortex of age-matched control brains (Good *et al.*, 1996; Smith *et al.*, 1997). These findings provide evidence that ONOO $^-$ may be involved in the inflammatory sequelae and oxidative damage of AD pathology. They also contribute to our understanding that NO and its activity can be detected in pathological states in the CNS.

Production of NO by Human Glia and Macrophages

Human Glial Cells

Because the production of iNOS and NO in the CNS has such potentially harmful effects on both neurons and oligodendrocytes and may play a role in such diseases as CNS AIDS, and MS, the cells of the nervous system may have evolved a protective mechanism to prevent spurious levels of NO formation even in the presence of iNOS gene induction (Xie *et al.*, 1992). We and others have shown that human fetal astrocytes and microglia respond to IFN- γ and IL-1 β by producing iNOS and mRNA within hours and iNOS protein within a day *in vitro*. However, in our experience, these cells do not make NO for a period of 24 to 48 hours after the appearance of the enzyme, at which time the production is between 10 and 20 μM ; this is so only if nitrate is reduced to nitrite before analysis using the Griess reagent (Lee *et al.*, 1993; Ding *et al.*, 1997; Ding and Merrill, 1997). Examining production of just nitrite within the first 24 to 48 hours usually reveals production of less than 10 μM (Lee *et al.*, 1993;

Hua *et al.*, 1998). Such a delayed NO production is in contrast to the appearance of iNOS and NO production by rodent glia *in vitro* within 8 to 24 hours of stimulation (Simmons and Murphy, 1992). Many human cells such as hepatocytes, chondrocytes, endothelial cells, and some glioblastoma cells have been shown to express iNOS and release large amounts of NO after stimulation with bacterial products and/or cytokines, showing similar kinetic patterns to that in rodent glial cells (Chakravarthy *et al.*, 1995; Blanco *et al.*, 1995; Grabowski *et al.*, 1996). Although human glial cells exhibit kinetics of iNOS transcription and translation in a time frame that is similar to other cell types, their kinetics of NO production is different compared to these other human cell types (Ding *et al.*, 1997; Ding and Merrill, 1997). Work from the laboratory of Dennis Stuehr has identified the fact that iNOS is not a functional enzyme until it is in a conformationally active state created by its dimerization (Baek *et al.*, 1993). The binding of heme and tetrahydrobiopterin (BH₄) to the enzyme play a significant role in forming and stabilizing active dimeric iNOS (Tzeng *et al.*, 1995). To understand if this temporal lag between iNOS enzyme synthesis and NO production was due to insufficient intracellular levels of the iNOS cofactor BH₄, we added BH₄ to the cultures. We were able to show a significant increase in NO production in a dose- and time-dependent manner, suggesting that the rate-limiting step in NO production in these human cells is cofactor induction and activation of functional iNOS enzyme (Ding *et al.*, 1997; Ding and Merrill, 1997).

As in rodent cultures, anti-inflammatory agents are able to inhibit NO production by human glia. In our laboratory, TGF- β , IL-4, IL-13, and IFN- β all inhibit NO and TNF- α production in human fetal glial cell cultures (St. Pierre *et al.*, 1996). IFN- β inhibited at lower concentrations than were required for inhibition by IL-13 and IL-4; furthermore, all the aforementioned cytokines inhibited TNF- α production better (e.g., at lower concentrations and to a greater degree) than they inhibited NO in these cultures. These findings support the observations that TNF- α does not directly induce NO and that the regulation of TNF- α and NO are dependent on different pathways. Although a separate study failed to find that IL-10 or TGF- β inhibited NO production, this same study and one other did confirm that nanomolar concentrations of IFN- β could inhibit NO production by human astrocytes (Guthikonda *et al.*, 1998; Hua *et al.*, 1998), and that the inhibition was at the transcriptional level (Hua *et al.*, 1998). Stewart *et al.* (1998), in a rodent culture system, demonstrated that NO-mediated damage by astrocytes to mitochondrial activities of complexes II/III, and IV in neighboring neurons is inhibitable by IFN- α/β . Compounds that raise cAMP will also inhibit NO production by human glia. Using the phosphodiesterase inhibitors pentoxifylline (PTX), rolipram, and isobutyl methyl xanthine (IBMX), we were able to demonstrate inhibition of both TNF- α and NO in human glial cell cultures; iloprost, a prostacyclin analog, was more potent than PTX or IBMX but less potent than rolipram in inhibition. As with the anti-inflammatory cytokines, TNF- α was more easily inhibited than NO (St. Pierre

et al., 1996). It has been observed in other cell systems in rodents that elevation of cAMP results in a downregulation of TNF- α and NO; the mechanism proposed has been through the inhibition of NF- κ B transcription or elevation of IL-10 (St. Pierre *et al.*, 1996). Rolipram and PTX have been successfully used *in vivo* in the EAE model to reduce disease, and IFN- β is used to treat MS patients (Mitrovic *et al.*, 1996; Parkinson *et al.*, 1997). It is therefore likely that these *in vivo* effects may well be due to the inhibition of the purported contributors to pathology, TNF- α and NO.

Human Macrophages

Whereas NO production in murine macrophages accumulates in a linear fashion following a lag of 6 hours after stimulation of cytokines (Evans *et al.*, 1994), human mononuclear phagocytes express iNOS mRNA and protein but produce no or little NO *in vitro* after such stimulation (Murray and Teitelbaum, 1992; Padgett and Pruett, 1992; Schneemann *et al.*, 1993; Albina, 1995). Although posttranslational regulation has been speculated to be the reason for this, some investigators have excluded the possibility of the regulation by BH₄, as increasing BH₄ levels do not enable the cells to produce high levels of NO (Weinberg *et al.*, 1995). This suggests that NO production in human glia and macrophages may be regulated differently. Clearly, glial cells and macrophages could respond differently to cytokine stimulation, thereby initiating different mechanisms for regulating iNOS catalytic activity. Studies in which tissues from humans with a variety of diseases have been examined have clearly shown that human macrophages do make iNOS and NO *in vivo* (see earlier) (Bagasra *et al.*, 1995; Nicholson *et al.*, 1996; Vodovotz *et al.*, 1996; Weinberg *et al.*, 1995). Again, whereas cross-linking of lectin-like receptors may be important in mimicking an endogenous signaling event in macrophages, and although cross-linking of cytokine receptors alone is not adequate for NO induction (at least *in vitro*), there are intriguing links between stress-induced neuroendocrine pathways and NO in these cells. β -Endorphin, a peptide released by the pituitary in response to stress, activates iNOS in human monocytes. The iNOS induction was dependent on a β -endorphin-triggered increase in cAMP (Aymerich *et al.*, 1998). This might indicate that stress-induced conditions are critical for macrophage activation and that more than one signal is required for NO induction in macrophages, thereby keeping a safety lock on the unnecessary triggering of a potentially harmful event *in vivo*.

NO/ONOO⁻ Role in MS Pathology

NO Production by Oligodendrocytes

Rodent oligodendrocytes respond *in vitro* to the cytokines IL-1 β and IFN- γ by iNOS/NO production; both of these cytokines have been implicated in MS (Murphy *et al.*, 1995; Merrill and Murphy, 1996). The production of NO by oli-

godendrocyte cultures is of interest, given that within the whole primary oligodendrocyte population, which is composed of bipotential precursors, committed oligodendrocytes, and mature myelin basic protein (MBP)-producing oligodendrocytes, there is a subset of NO-sensitive cells (Mitrovic *et al.*, 1995, 1996; Merrill *et al.*, 1993). Primary rat oligodendrocytes produce NO as a consequence of the induction of the iNOS gene. Inhibition of transcription or translation results in the absence of iNOS protein in oligodendrocytes and the lack of detectable NO in the culture supernatants. The protein and mRNA are identical in size to those induced in other human and rodent glial cells (Merrill *et al.*, 1997). The levels of iNOS and mRNA and the function of iNOS enzyme *in vitro* (as determined by L-citrulline production) indicate that microglia are better producers than oligodendrocytes and astrocytes. Alveolar macrophages appear to be better producers than brain microglia under the conditions tested. The fact that oligodendrocytes can produce NO may not be surprising, given that Gold *et al.* (1996) have demonstrated iNOS activation in the myelinating cell in the peripheral nervous system, the Schwann cell. Some NO-producing cells seem to be refractory to NO-mediated toxicity, as in the case of microglia and NOS-positive neurons (Dawson and Dawson, 1994; Mitrovic *et al.*, 1994). Cells such as astrocytes, macrophages, and hepatocytes, while insensitive to self-injury from endogenously produced NO, may be more sensitive to exogenous NO from a neighboring cell. Nevertheless, these cells seem to be able to repair the NO-mediated damage, possibly by converting to glycolysis during the repair phase (Drapier and Hibs, 1988; Stadler *et al.*, 1991; Mitrovic *et al.*, 1994). In the case of oligodendrocytes, it will be important to determine whether the NO-producing oligodendrocytes are also insensitive to their own chronically produced endogenous NO.

Free Radical-Mediated Oligodendrocytes and Myelin Damage

The brain is considered a target for oxidative stress and formation of lipid peroxides for several reasons: (a) large O₂ stores are required for maintenance of electrical activity, (b) phospholipids containing fatty acids with multiple bonds are more ubiquitous than in peripheral tissue, (c) free divalent iron is elevated in the brain, (d) reduced glutathione (GSH) is low in the nervous system, (e) there are elevated levels of enzymes generating active oxygen and nitrogen species in the CNS, and (f) there are cells in the CNS that are exquisitely sensitive to free radical injury such as neurons and oligodendrocytes (Thorburne and Juurlink, 1996; Glozman and Yavin, 1997).

In models of trauma and disease *in vivo* and *in vitro*, oligodendrocytes are easily damaged. Rodent microglia or macrophages will produce free radicals and kill oligodendrocytes when activated by virus or following cross-linking of cytokine receptors, FcR, or cell surface adhesion molecules such as ICAM-1 (intracellular adhesion molecule-1) (Griot *et al.*, 1990; Zajicek *et al.*, 1992; Ulvestad *et al.*, 1994; Mer-

rill and Benveniste, 1996). This killing can be inhibited by antibodies to TNF- α or adhesion molecules, by anti-inflammatory cytokines such as TGF- α , or by free radical scavengers (Griot *et al.*, 1990; Merrill and Benveniste, 1996). Microglial cytotoxicity and NO production appear to be mediated partially and indirectly by TNF- α . That is, TNF- α does not induce NO by itself, nor can soluble TNF- α directly kill oligodendrocytes; TNF- α associated with the cell surface of microglia may play a role in the cytotoxicity (Zajicek *et al.*, 1992; Merrill *et al.*, 1993; Merrill and Benveniste, 1996). When exposed to reactive oxygen species (ROS) or NO or inducers of free radicals *in vitro* or *in vivo*, the oligodendrocyte is more vulnerable to injury than are microglia or astrocytes (Griot *et al.*, 1990; Ulvestad *et al.*, 1994; Juurlink and Husain, 1994; Husain and Juurlink, 1995; Mitrovic *et al.*, 1994, 1995, 1996; Thorburne and Juurlink, 1996). CSF from MS patients induces oligodendrocyte damage *in vitro* via glial cell-produced NO (Xiao *et al.*, 1996). Hypoxic-ischemic conditions cause white matter damage and oligodendrocyte death (Rice *et al.*, 1980; Qi and Dawson, 1993). Oligodendrocytes are exquisitely sensitive to lipid peroxidation caused by free radicals produced under anoxia (Husain and Juurlink, 1995). It has also been shown that electrical conduction in demyelinated and newly remyelinated axons is particularly sensitive to direct inhibition by NO (Redford *et al.*, 1997). Nitric oxide can impair mitochondrial function in oligodendrocytes and astrocytes (Mitrovic *et al.*, 1994; Bolaños *et al.*, 1994), and it induces a necrotic-like cell death in oligodendrocytes *in vitro* (Merrill *et al.*, 1993; Mitrovic *et al.*, 1995). Nevertheless, not all oligodendrocytes from primary brain cultures are killed by NO. Indeed, we have discovered NO-resistant oligodendrocyte cell lines, suggesting that there are differential sensitivities among maturational subsets of oligodendrocytes to the toxic effects of this molecule (Mackenzie-Graham *et al.*, 1994; Mitrovic *et al.*, 1994; Juurlink *et al.*, 1998). As noted above, a cell that makes NO may be able to protect itself from such toxic effects on intracellular proteins. This seems to be the case for microglial cells (Simmons and Murphy, 1992; Mitrovic *et al.*, 1994) and astrocytes (Bolaños *et al.*, 1994).

Reduced glutathione (GSH), as an electron donor, scavenges hydrogen peroxide (H₂O₂) and organic peroxides in a biochemistry catalyzed by glutathione peroxidase (GPx). If lipid peroxides are not scavenged, Fe²⁺ will drive H₂O₂ to \cdot OH (hydroxyl radical) and convert lipid hydroperoxides to alkoxyl radicals; Fe³⁺ will lead to peroxy radicals. Juurlink *et al.* (1998) report that oligodendrocytes have 23-fold more iron than astrocytes, while having only half the amount of GSH and less than 15% of the levels of GPx as astrocytes (Thorburne and Juurlink, 1996). Exposure of oligodendrocytes to glutamate induces cystine depletion through the action of a glutamate-cystine exchange, thereby depleting glutathione and causing free radical-mediated cell death (Yonezawa *et al.*, 1996; Oka *et al.*, 1998). In preliminary work from the Merrill laboratory, oligodendrocytes appear to be producing lower levels of manganese superoxide dis-

mutase (SOD) than microglia or astrocytes in the presence of inflammatory stimulators. Requirements for iron during myelination by immature oligodendrocytes may lead to an undesirable mismanagement of iron in oligodendrocytes as the result of iron acquisition (via transferrin receptors) and storage (via ferritin) (Connor and Menzies, 1995, 1996). In other words, stress during situations where myelin turnover or repair is required might in fact lead to risk for the oligodendrocyte. This hypothesis might shed light on the previously mentioned *in vitro* observation that mature oligodendrocytes produce NO (Merrill *et al.*, 1997) and are less sensitive to the effects of NO than more immature oligodendrocytes (Mackenzie-Graham *et al.*, 1994). Free radical damage to cells must then be considered in the context of not only the state of maturation of the cell, but also the concomitant production of endogenous free radicals in the presence of defense mechanisms to protect against the consequences of this biological activity.

Regulation of Molecules at the Blood–Brain Barrier

The Th1 response, which has been shown to be critical in unmasking latent EAE in resistant mouse strains, has been shown to be driven by IL-12 (Segal and Shevach, 1996). The transcription of the p40 chain of the IL-12 heterodimer is regulated by NO (Rothe *et al.*, 1996). Blocking ROS or NO production with mitochondrial inhibitors or antioxidants abrogates transcription of and subsequent production of these proinflammatory cytokines (Schulze-Osthoff *et al.*, 1993; Ziegler-Heitbrock *et al.*, 1993; St. Pierre *et al.*, 1996), supporting the hypothesis that free radicals can regulate gene transcription and subsequent events at the BBB. Activation and contact between blood-borne inflammatory cells and cerebrovascular endothelial cells (EC) involves ICAM-1 on EC and its integrin receptor on leukocytes, the lymphocyte function-associated antigen-1 (LFA-1). Cross-linking of ICAM-1 activates T cells and macrophages, resulting in the production of proinflammatory molecules IFN- γ , IL-1 β , and NO (Merrill *et al.*, 1993; Merrill and Benveniste, 1996; Koyama *et al.*, 1996). When cytokines are induced and NO produced, there is an alteration in the permeability of the BBB, an increase ICAM-1 and LFA-1, and induction of another adhesion molecule, vascular cell adhesion molecule-1 (VCAM-1), on EC and glia. VCAM-1 is a ligand for the integrin very late antigen-4 (VLA-4). It is the expression of VLA-4 and its interaction with VCAM-1 that are crucial for the preferential entry of CD4⁺ T cells into the CNS (Schenk *et al.*, 1996; Baron *et al.*, 1993). Additionally, HLA-DR, a class II major histocompatibility complex molecule noted for its role in antigen presentation, is also likely to be critical for T cell adhesion to EC (Goodall *et al.*, 1992; Masuyama *et al.*, 1986; Schenk *et al.*, 1996). IL-1 β , TNF- α , IL-6, and NO are all elevated in EAE and MS (Murphy *et al.*, 1995; Merrill and Murphy, 1996). NF- κ B influences the inflammatory response and affects those cytokines and chemokines influencing BBB permeability and cell trafficking into the CNS: IL-1 β , IL-6, TNF- α , IFN- γ , the colony stimulating factors (CSFs), IL-8,

MCP-1, HLA-DR, VCAM-1, and ICAM-1 (Dröge *et al.*, 1994; Raes *et al.*, 1995). NO and reactive oxygen intermediates (ROI) increase TNF- α , IL-6, and IL-1 β gene expression *in vitro* and *in vivo* (Magrinat *et al.*, 1992; Eigler *et al.*, 1993).

In mice, IFN- γ or lipopolysaccharide (LPS)-induced MHCII, is inhibited by NO donor agents or stimulants that induce NO (Sicher *et al.*, 1994, 1995). In vascular smooth muscle cells and EC, NO inhibits ICAM-1 and VCAM-1 (De Caterina *et al.*, 1995; Shin *et al.*, 1996). Inhibition of Na⁺/K⁺-ATPase by ouabain activates NF- κ B, leading to the expression of VCAM-1 and iNOS (Bereta *et al.*, 1995). Activator protein 1 (AP-1)-dependent transcriptional activation in some cells can be induced both by pro- and antioxidant conditions. Pyrolidone dithiocarbamate (PDTC) induces ICAM-1 via the stimulation of *c-fos* and *c-jun* binding to the AP-1 consensus site (Meyer *et al.*, 1993; Muñoz *et al.*, 1996), suggesting that ICAM-1 and VCAM-1 are upregulated by prooxidants through NF- κ B. This finding might fit with the observation that these adhesion molecules are usually inhibited by scavengers such as NO and PDTC (Marui *et al.*, 1993; De Caterina *et al.*, 1995), though ICAM-1 can be upregulated by antioxidants through the AP-1 site. ROS can also regulate the amplification of cells and their migration across the BBB. Oxygen intermediates induce, while NO inhibits, macrophage colony-stimulating factor (M-CSF) (Satriano *et al.*, 1993; Peng *et al.*, 1995). Because the thiol compound diethyldithiocarbamate (DDTC) increases M-CSFs in other cells, there is the suggestion that NO may be acting as an oxygen radical scavenger, preventing M-CSF gene transcriptional activation (East *et al.*, 1992). Thus, NO influences the nature of the cytokines and the subsequent production or inhibition of molecules on trafficking leukocytes and EC, which will affect cell migration into the CNS parenchyma.

Once cells have crossed the BBB, they are directed to migrate toward gradients created by chemoattractant cytokines. These small chemokines can be cell specific in determining the immigration patterns of lymphocytes and macrophages to certain inflammatory regions, and they are also capable of enhancing activation by integrins through redistribution of adhesion molecules, thereby modulating leukocyte–EC interactions (Del Pozo *et al.*, 1995; Ransohoff *et al.*, 1996). NO inhibits expression of the chemokines IL-8 and MCP-1 in EC (De Caterina *et al.*, 1995; Zeiher *et al.*, 1995). However, NO upregulates IL-8 transcription in leukocytes and melanoma cells (Remick and Villarete, 1996). ROS (H₂O₂ · OH) and also paraquat upregulate IL-8 in stimulated cells, whereas antioxidants such as DMSO, mannitol, ethanol, and thiourea inhibit this induction (DeForge *et al.*, 1992; Bianchi *et al.*, 1993; Remick and Villarete, 1996; Tanaka *et al.*, 1997). Thus, NO can affect events subsequent to migration of cells across the BBB. Clearly, NO/ONOO[−] may influence the activation and migration of T cells across the BBB; by regulating gene expression of MHCII and adhesion molecules, as well as chemoattractants, NO can be either pro- or anti-inflammatory during the generation of CNS lesions. Nevertheless, once NO is induced in the context of

vulnerable cells whose function is altered in the presence of free radicals as in the brain parenchyma, it may contribute to pathology.

CNS Inflammation in EAE

Immunization of animals with one of the myelin proteins (MBP), proteolipid protein (PLP), or myelin-oligodendrocyte protein (MOG) induces EAE, the most widely used model for MS. In this model, helper T (Th) lymphocytes specific for myelin proteins are essential for EAE development (Mokhtarian *et al.*, 1984; Zamvil *et al.*, 1985; Lemire and Weigle, 1986; van der Veen *et al.*, 1990). The pathogenesis of EAE involves the infiltration of activated myelin-specific T cells into the CNS, where they initiate inflammation, setting off a chain of events leading to, among others, the phagocytosis of myelin by macrophages.

Th1 versus Th2 Paradigm

Th cells differentiate into at least two functionally distinct subsets (Cher and Mosmann, 1987). Inflammatory Th1 cells characteristically produce IL-2, IFN- γ , and lymphotoxin, whereas Th2 cells produce IL-4, IL-5, IL-6, and IL-10 (Cher and Mosmann, 1987; Mosmann and Coffman, 1989; Gajewski *et al.*, 1989). Th1 and Th2 cells are reciprocally inhibitory (Fiorentino *et al.*, 1991): the Th2 products IL-4 and IL-10 inhibit Th1 cell differentiation or activation. IL-4 induces Th2 cell differentiation (Mosmann, 1991; Gautam *et al.*, 1992; Powrie *et al.*, 1993), whereas Th1 cell differentiation is induced by IL-12 and IFN- γ (Hsieh *et al.*, 1993). Similar but not identical differences are observed among human Th cells (Maggi *et al.*, 1992; Taga and Tosato, 1992). Myelin-specific Th subsets have also been demonstrated in MS (Voskuhl *et al.*, 1993; Correale *et al.*, 1995).

Traditionally, the CNS and some other tissues are thought to be relatively immune-privileged sites, indicative of the absence of routine immune surveillance. Initially, this was thought to be a passive process solely due to the blood-brain barrier; more recently, however, the active nature of immune privilege has been suggested (Streilen, 1993), and the concept of the brain as an immunoincompetent site is being scrutinized. A direct link between the brain and cerebral lymph nodes has been suggested (Cserr and Knopf, 1992). Intracerebrally introduced antigens are at least as immunogenic as in extracerebral sites (Gordon *et al.*, 1992), although the mechanism by which antigens in the brain are processed and presented to T cells remains unclear.

The concept of cross-regulatory Th subsets could be of particular significance to CNS inflammation. Immune privilege may be synonymous with noninflammatory immunity, or with suppression of inflammation. In the case of the brain, suppression of inflammation is likely to be crucial (Cserr and Knopf, 1992; Harling-Berg *et al.*, 1991), because of the particular vulnerability of the brain for inflammatory processes. Studies suggest that brain cells produce anti-inflammatory

cytokines during the first days following a viral infection in the CNS, whereas the appearance of proinflammatory cytokines coincides with the onset of CNS inflammation (Weselingh *et al.*, 1992). Th1 cell products stimulate TNF- α production in macrophages and microglia, which is considered important in demyelination (Renno *et al.*, 1995) and is downregulated by IL-10 (Fiorentino *et al.*, 1991). Involvement of IL-10 (Kennedy *et al.*, 1992; Rott *et al.*, 1994) or IL-4 (Racke *et al.*, 1994) in EAE remission or inhibition has been suggested. These arguments strongly implicate Th2-type cytokines in the regulation of CNS inflammation by Th1 cells. However, it remains to be proved which anti-inflammatory brain-derived products are important during remissions, and what their source is. A central role for Th2 cells in EAE remissions has become less likely (Khoruts *et al.*, 1995; Lafaille *et al.*, 1997).

Nitric Oxide in EAE

Free radicals, particularly the reactive oxygen intermediates, are thought to be involved in inflammatory processes (Winrow *et al.*, 1993) by exacerbating inflammation and causing tissue damage. The role of free radicals in the induction of inflammation involves the expression of inflammatory mediators, such as cytokines, adhesion molecules, and eicosanoids (Halliwell and Gutteridge, 1995). CNS tissue is particularly vulnerable to oxidative damage (Konat and Wiggins, 1985; Griot *et al.*, 1990; Fisher *et al.*, 1993; Dawson and Dawson, 1994; Bongarzone *et al.*, 1995; Connor and Menzies, 1995, 1996; Thorburne and Juurlink, 1996; Yonezawa *et al.*, 1996; Glozman and Yavin, 1997; Smith *et al.*, 1997), suggesting that any form of oxidation could be an important factor in the pathogenesis of CNS inflammation in MS and EAE. Several reports indirectly implicate free radical involvement in autoimmune CNS inflammation. For instance, antioxidant treatment ameliorates EAE (Ruuls *et al.*, 1995; Hansen *et al.*, 1995).

The free radical species that has been most convincingly linked to MS or EAE activity is nitric oxide (NO), because the inhibition of NOS inhibits disease progression in animal models *in vivo* and oligodendrocyte cell death *in vitro* (Merrill *et al.*, 1993; Mitrovic *et al.*, 1994; Cross *et al.*, 1994; Bagasra *et al.*, 1995; Zielasek *et al.*, 1995; Zhao *et al.*, 1996; Ding *et al.*, 1998). Type II NOS can be induced in endogenous glia in the CNS (microglia and astrocytes) and in inflammatory cells invading from the blood; NO production in EAE and MS tissues can be validated by electron paramagnetic resonance spectroscopy and spin trap technologies as well as footprinting the production of NO via the presence of nitrotyrosine and elevated cGMP levels (Mitrovic *et al.*, 1996). Constitutive isoforms of NOS are present in endothelial cells and neurons (Knowles and Moncada, 1994). During inflammation, the NO concentration in the CNS increases substantially (Hooper *et al.*, 1995; Okyda *et al.*, 1995). Furthermore, in EAE, encephalitogenic T cells stimulate NO production by macrophages (Misko *et al.*, 1995). Independent studies from at least four laboratories, using both the rat

and mouse models of EAE, have demonstrated that NO is involved in EAE development and progression (reviewed in Parkinson *et al.*, 1997). However, two additional studies have demonstrated variable consequences (Zielasek *et al.*, 1995) or aggravated EAE (Ruuls *et al.*, 1996) following inhibition of NOS. Furthermore, iNOS-deficient mice develop more severe EAE than normal mice (Fenyk-Melody *et al.*, 1998; Sahrbacher *et al.*, 1998).

There are several explanations for the seemingly irreconcilable differences in the effects of antagonizing NOS in the various models, which have been dealt with fully elsewhere (Parkinson *et al.*, 1997). In brief, however, the doses used in the acute rat model, where inhibition of NOS failed to protect, were lower than optimal, and the route of administration was different from that used in the mouse models. Additionally, neither of the negative studies demonstrated that the administration of a NOS inhibitor actually inhibited iNOS *in situ* nor that NO production in the affected tissue was blocked. Such data are important in the evaluation of the results. Furthermore, more information on the bioavailability of aminoguanidine and other standard NOS analog inhibitors in the CNS of rats and mice is necessary to help rationalize these conflicting data and instruct us in the future use of such compounds for treating inflammation in the spinal cord and brain.

Although the scientific documentation for a role for NO in cell death or damage is strong, several lines of evidence indicate that NO may in fact be protective under certain circumstances, perhaps best illustrated by the NO-deficient mouse models (see earlier). For instance, the NO molecule is a weak oxidant, but it reacts more rapidly as an antioxidant (Hogg *et al.*, 1993). Many nontoxic functions have been ascribed to NO, namely, smooth muscle relaxant and neurotransmitter. Interestingly, NO may even protect against lipid peroxidation (Jessup *et al.*, 1992; Hogg *et al.*, 1993; van der Veen and Roberts, 2000), and it may be involved in protection against cytokine-induced damage (Matthys *et al.*, 1995) as well as in inhibition of leukocyte adhesion and migration through the endothelial cell layer (Kubes *et al.*, 1994). In addition, NO has been implicated as a major macrophage-derived immunosuppressive factor for T-cell immunity (Mills, 1991; Tomioka and Saito, 1991) and as an inhibitor of NF- κ B activation in the CNS (Togashi *et al.*, 1997). Clearly, depending on the chronicity of production, concentrations reached, and the temporal and spatial production of NO, this molecule may function as either a pro- or anti-inflammatory mediator.

Some reports have raised the possibility that NO is involved in the differential regulation of Th subsets. NO reportedly inhibits Th1 but not Th2 cell stimulation *in vitro* (Taylor-Robinson *et al.*, 1994). Th1 cells (but not Th2 cells) produce NO as well, suggesting an autoregulatory pathway in Th1 cells. Furthermore, iNOS-deficient mice, besides clearing pathogens less well, develop stronger Th1-type immune responses (Wei *et al.*, 1995), suggesting that NO has a potential role in regulating the balance between Th subsets *in vivo* as well. However, this concept has been challenged

(Nukaya *et al.*, 1995). This laboratory has demonstrated that NO derived from an NO donor inhibits both Th1 and Th2 clones to a similar degree (R. C. van der Veen *et al.*, unpublished observation). This indicates that NO inhibits the activation of differentiated T cells from both Th subsets, although it does not exclude the possibility for a role of NO in the differentiation of uncommitted Th cells during the early stages of an immune response. Interestingly, the inhibition by NO was very specific for T-cell proliferation. Other functions, most notably the production of cytokines, were not critically affected. Similar results were obtained with NO produced by macrophages.

PEROXYNITRITE IN EAE

NO can be transformed by the free radical superoxide (O_2^-) to form the powerful oxidant peroxynitrite ($ONOO^-$). Peroxynitrite induces lipid peroxidation (Beckman, 1994) and may thus be involved in myelin degradation. NO-induced neuronal damage is mediated by peroxynitrite (Ohkuma *et al.*, 1995; Bolaños *et al.*, 1995). These findings suggest that peroxynitrite mediates damage in the CNS. Peroxynitrite-like activity has been demonstrated in the inflamed CNS (Hooper *et al.*, 1997; van der Veen *et al.*, 1997; Cross *et al.*, 1998). Indeed, Hooper *et al.*, (1997) reported the inhibition of EAE with the presumed peroxynitrite scavenger uric acid. Interestingly, NO levels in the CNS of these protected mice were still elevated, suggesting that NO may not be the major detrimental factor in this disease.

Peroxynitrite may represent at least part of the NO-associated toxicity, especially for its strong induction of lipid peroxidation. Lipid peroxidation causes arachidonic acid to be transformed into prostaglandin-like, but cyclooxygenase-independent F2-isoprostanes (Morrow *et al.*, 1992; Takahashi *et al.*, 1992). Likewise, docosahexaenoic acid (C22:6) is transformed into neuroprostanes, novel products that are formed in the CNS and testes only. Besides serving as markers of lipid peroxidation, isoprostanes may exert strong biological effects (Hooper *et al.*, 1997). We demonstrated the formation of F2-isoprostanes and neuroprostanes in peroxynitrite-treated myelin *in vitro*, as well as in EAE. Interestingly, NO inhibited peroxynitrite-induced lipid peroxidation in myelin (van der Veen and Roberts, 1999).

Lipid peroxidation by peroxynitrite results in the phagocytosis of the oxidized low density lipoprotein (LDL) by macrophages, which has been studied extensively in relation to atherosclerosis. Phagocytosis of oxidized LDL was demonstrated to involve specific receptors on macrophages separate from the scavenger receptors (Ottanad *et al.*, 1995). Receptors for oxidized LDL may recognize oxidized lipids or lipid-protein complexes in general, since they are also involved in the uptake of oxidized erythrocytes (Ottanad *et al.*, 1995). Phagocytosis of oxidized LDL has been shown to occur in MS plaques (Newcombe *et al.*, 1994), indicating that a similar process may occur with oxidized myelin as the target. Although peroxynitrite may be important in EAE, it may not be essential for this condition, since iNOS-deficient mice develop severe EAE (Fenyk-Melody *et al.*, 1998;

Sahrbacher *et al.*, 1998). The formation of peroxynitrite in these mice is unknown, but in the absence of strong NO fluxes from iNOS, peroxynitrite supposedly will not be formed in high quantities, even locally. In our experience, peroxynitrite-like activity, as indicated by nitrotyrosine staining, was restricted to phagocytes during EAE (van der Veen *et al.*, 1997), indicating that constitutive forms of NOS may not produce enough NO for peroxynitrite formation. However, the formation of low but undetectable levels of peroxynitrite cannot be ruled out.

Superoxide Anion Regulation of NO Activity in EAE

Most recently, our laboratory has studied the T-cell inhibitory role of NO (see earlier) in relation to EAE, based on the strong expression of iNOS in cells in the CNS during EAE, of which only a subfraction coexpressed peroxynitrite-like activity (van der Veen *et al.*, 1997). Since O_2^- has a strong affinity for NO, the possibility was studied that superoxide regulates the effect of NO on T cells. Peritoneal macrophages completely inhibited the proliferation of pre-stimulated, myelin-specific T cells, which was reversed in the presence of high levels of a NOS inhibitor (L-NMA). In the presence of low levels of L-NMA, which induced only a slight increase in T-cell proliferation, a substantial increase was induced when phorbol ester (PMA) was added simultaneously (Fig. 1A). The further addition of SOD reversed the effect of PMA, indicating that O_2^- production is responsible for the inactivation of NO. Neither PMA itself nor O_2^- or H_2O_2 had a substantial direct effect on T-cell proliferation. The presence of low levels of L-NMA was important to observe this effect, because in its absence, PMA only slightly inactivated NO. Apparently in this situation the NO production overwhelms or simply inhibits the O_2^- production (Ruuls *et al.*, 1995; Hansen *et al.*, 1995).

ROLE OF NADPH OXIDASE IN THE REGULATION OF NO ACTIVITY

Since extracellular SOD inhibited the effect of O_2^- on NO activity, and since O_2^- cannot penetrate the cell membrane, the O_2^- appears to be produced extracellularly. An important source for extramembraneous O_2^- production is NADPH oxidase. Therefore, the T-cell regulation by macrophages from NADPH oxidase-deficient [p47^{phox}(KO) knockout] mice became a key model in which to address this issue.

The degree to which macrophages derived from p47^{phox} KO mice were able to inhibit the effect of NO on T cells can be examined by determining if NADPH oxidase forms a major source of NO-inactivating O_2^- . Peritoneal exudate cells (PEC) from normal wild-type (WT) and p47^{phox} KO mice inhibited T-cell proliferation equally well, which was reversed with high levels of L-NMA, as expected. In the presence of low levels of L-NMA, stimulation with PMA reversed the inhibitory effect of NO in WT mice (Fig. 1B). However, in KO mice the addition of PMA had no effect, demonstrating that the lack of functional NADPH oxidase results in the preservation of NO activity. This suggests that

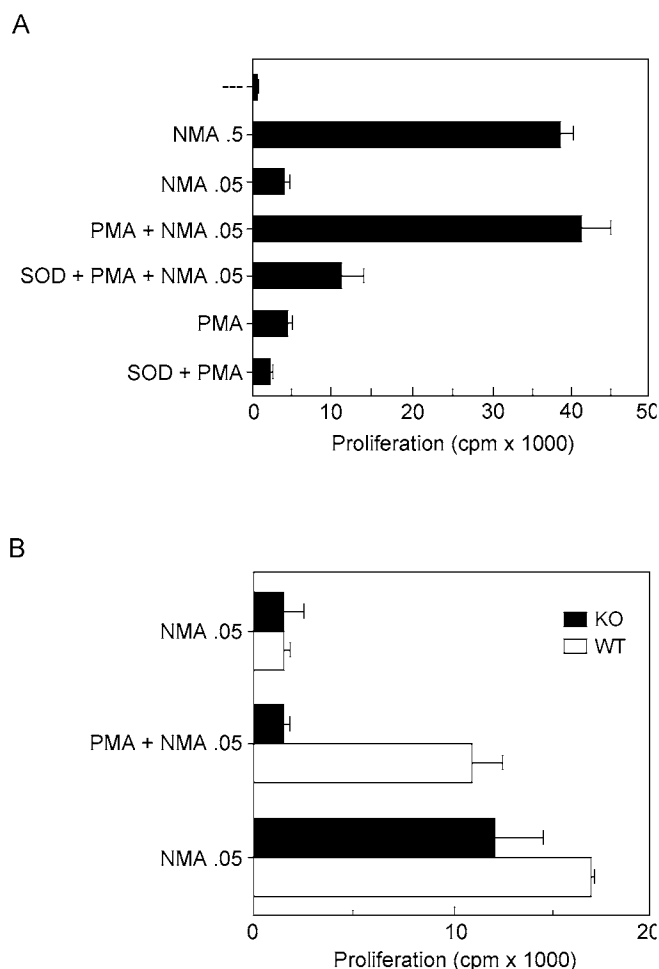

Figure 1 (A) Superoxide reverses the inhibitory effect of NO. Normal PEC were stimulated with IFN- γ and LPS, while cloned Th cells were stimulated with anti-CD3 monoclonal antibody separately. After 16 hours, the stimulated T cells were transferred to the PEC cultures in the presence of L-NMA (NMA), PMA, or SOD as indicated, and simultaneously pulsed with [3 H] TdR. (B) Cells from NADPH oxidase-deficient mice do not inhibit NO activity. Similar cocultures were set up with PEC from normal wild-type (WT) or p47^{phox} knockout (KO) mice.

O_2^- production by NADPH oxidase inhibits the activity of NO in normal PEC.

Apparently, other oxidases besides NADPH oxidase do not contribute substantially to the NO-neutralizing O_2^- production, at least not in this system, which is centered around the induction of oxidases by PMA. Possibly, the localization (and timing) of O_2^- production as well as its quantity are crucial. A schematic representation of the possible sequence of events leading to either NO or ONOO $^-$ production is shown in Fig. 2. Intracellularly produced NO diffuses freely through the cell membrane, and it inhibits T-cell proliferation if NO remains unaffected by O_2^- (owing to the presence of SOD or a mutation in NADPH oxidase). However, when NADPH oxidase is activated and assembled in the cell membrane simultaneously, it produces O_2^- extracellularly, which binds NO, while it is just on its way out of the cell.

Figure 2 Schematic representation of the regulation of NO activity by O_2^- . See text for explanation.

This leads to the formation of $ONOO^-$ outside of the cell, simultaneous with the inactivation of NO and subsequently the proliferation of T cells, among others.

There may be many biological consequences of the processes described here. If NO is left intact, it can regulate immune activity in inflamed tissue, or it can serve as an antioxidant during oxidative processes such as lipid peroxidation. If, on the other hand, peroxynitrite is formed, it induces oxidative damage such as lipid peroxidation. This may damage the tissue locally and result in enhanced myelin degradation. At the same time, the immune-regulatory activity of NO is lost, resulting in the enhancement of inflammatory processes, further aggravating tissue damage. Thus, NO presents a double-edged sword: either it is antiinflammatory (as NO) or proinflammatory (as $ONOO^-$), which is regulated by O_2^- produced by NADPH oxidase. This dualism may explain the controversy over the role of NO in CNS inflammation.

ROLE OF NADPH OXIDASE IN EAE

Based on the data presented here, our prediction was that NADPH oxidase-deficient mice develop EAE to a lesser degree than normal mice. Indeed, the disease expression in these KO mice was not just less severe than in normal mice, it was virtually absent, both clinically and histologically. This indicates that NADPH oxidase forms an essential component in the development of EAE. Besides a direct role for reactive oxygen species in EAE development, this result could also indicate that NO suppresses EAE in the absence of O_2^- from NADPH oxidase, whereas in its presence NO is inhibited enough for EAE to develop. The generation of immunity was apparently normal in the KO mice, since lymph node cells from immunized KO mice proliferated just as well in response to the immunogen *in vitro* as lymph node cells from wild-type mice. On the other hand, spleen cells from

NADPH oxidase KO mice showed only a weak or, more frequently, no proliferative response to the immunogen at all. In contrast, spleen cells from wild-type mice responded well. Despite the absence of proliferation in the KO mice, their spleen cells responded to the encephalitogen with cytokine production to a similar degree as wild-type mice. Since only the proliferation of spleen cells, not the cytokine production, was inhibited in the KO mice, the resemblance with the effect of NO on T-cell stimulation (see earlier) became apparent.

Therefore, the proliferation of spleen cells was tested in the presence of L-NMA, which indeed uncovered a good proliferative response to the immunogen in KO spleen, whereas only slightly increasing proliferation in most normal spleen cells (Fig. 3). This indicates that in the absence of

Figure 3 NADPH oxidase-deficient spleen cells display stronger NO activity. Spleen cells from KO and WT mice, previously immunized with myelin oligodendrocyte glycoprotein 35-55 in complete Freund's adjuvant, were incubated with MOG 35-55, some in the presence of L-NMA (1 mM).

NADPH oxidase, a spleen cell subpopulation produces enough NO during an immune response *in vitro* to inhibit the proliferation of T cells completely, although NO is less active in spleens from normal mice. These NO-producing spleen cells may be the same as the more recently described splenic Sca1/Mac1⁺ macrophages, which suppress T-cell responses with their NO production (Johnson *et al.*, 1998). Apparently, O₂⁻ production by NADPH oxidase inactivates NO in the spleen environment in normal mice.

In conclusion, O₂⁻ from NADPH oxidase was shown to regulate the inhibitory activity of NO toward T-cell proliferation. This was shown both in isolated adherent PEC as well as in total spleen cell cultures. In addition, NADPH oxidase-deficient mice are resistant to EAE induction, indicating that NO may be highly active in these mice. In other words, the balance between O₂⁻ and NO may regulate the extent of an immune response. This may also hold true in target tissues, such as the CNS, where NO could downregulate inflammatory responses if left untouched by O₂⁻. If indeed a central role for NO in immune responses *in vivo* can be confirmed, this would be of extreme significance to many disorders, both inflammatory or infectious, in which the activity of NO (not simply its production) could be either too low or too high, respectively.

Conclusions

Overall, it seems fair to think that the evolution of the disease pathology in both EAE and MS involves NO. Macrophages and microglia appear to be the major producers of NO and ONOO⁻. Early in the disease induction, NO may be anti-inflammatory in that NO reduces T-cell clonal expansion and inhibits induction of adhesion molecules and MHC class II molecules, thereby inhibiting trafficking of and antigen presentation by blood-borne cells into the CNS. Nevertheless, as a consequence of such cellular movement into the CNS and recruitment of endogenous glia, the continued production of NO in the parenchyma of the brain certainly affects myelin and the myelin-producing cell the oligodendrocyte in a negative way. Future challenges to a fuller understanding of the mechanisms of action of NO in the chronic progression of disease include the development of more precise techniques for measurement of endogenous NO levels in CSF and brain and spinal cord tissue. Our ability to detect NO metabolites and track the "footprints" of peroxynitrite formation will be of value in designing clinical protocols and assessing outcomes of therapeutic agents that inhibit iNOS and NO.

Role of Nitric Oxide in the Regulation of Blood Flow

T. M. Griffith

*Department of Diagnostic Radiology, Wales Heart Research Institute,
University of Wales College of Medicine, Cardiff, United Kingdom*

LOCAL HEMODYNAMIC FORCES ACTIVELY REGULATE VASCULAR SMOOTH MUSCLE TONE THROUGH THE PHENOMENON OF FLOW-DEPENDENT DILATION, WHICH IS PRINCIPALLY MEDIATED VIA NITRIC OXIDE (NO) RELEASED BY THE ENDOTHELIUM. THIS DYNAMIC RESPONSE CONTRIBUTES TO THE HYDRAULIC EFFICIENCY OF THE CIRCULATION AND OPTIMIZES PERFUSION BY INTERACTING WITH MYOGENIC AND METABOLIC CONTROL MECHANISMS. THE ABILITY OF THE ENDOTHELIAL CELL TO SENSE SHEAR STRESS INVOLVES AN ARRAY OF SIGNALING PATHWAYS AND CELLULAR COMPONENTS, INCLUDING G PROTEINS, CAVEOLAE, INTEGRINS, AND THE CYTOSKELETON, WHICH MAY ALL PARTICIPATE IN THE MECHANOTRANSDUCTION MECHANISMS THAT LEAD TO THE ACTIVATION OF THE ENDOTHELIAL NO SYNTHASE (eNOS). ON A LONG-TERM BASIS, REGULATION OF eNOS BY SHEAR FORCES IS THOUGHT TO CONTRIBUTE TO THE ABILITY OF THE VESSEL WALL TO REMODEL AND THEREBY NORMALIZE SHEAR STRESS FOLLOWING SUSTAINED CHANGES IN FLOW. FURTHERMORE, MOMENT-TO-MOMENT RELEASE OF NO AND EXPRESSION OF eNOS ITSELF ARE DIFFERENTIALLY REGULATED BY STEADY, PULSATILE, AND TURBULENT SHEAR FORCES. THIS SENSITIVITY TO DIFFERENT FLOW PATTERNS MAY EXPLAIN WHY CERTAIN SITES IN THE CIRCULATION ARE PREDISPOSED TO THE DEVELOPMENT OF DISEASE.

Introduction

Schretzenmayr first described flow-dependent increases in the diameter of the canine femoral artery as early as 1933, but nearly 50 years were to elapse before Furchgott and Zawadzki (1980) “serendipitously” discovered the importance of the endothelium in the regulation of vascular tone—a pivotal observation that has provided the key to understanding how hemodynamic forces influence local vascular resistance. It is now well established that nitric oxide (NO) synthesis by the constitutive endothelial NO synthase (eNOS or NOS type III) is stimulated by longitudinal shear forces acting on the endothelium as a result of blood flow, as well as by agonist occupation of endothelial membrane receptors. Flow-dependent release of NO allows efficient and dynamic

coupling of downstream metabolic demands with upstream resistance, and its interaction with pressure-sensitive and metabolic mechanisms of regulating smooth muscle tone contributes to the integration of vascular control mechanisms and the optimization of organ perfusion. Many aspects of the flow-dependent response nevertheless remain poorly understood, and the mechanotransduction pathways that allow the endothelial cell to sense and respond to physical forces remain a focus of active research. Indeed, there are major differences in the pathways that lead to NO synthesis in response to pharmacological and to mechanical stimuli, as agonist-stimulated responses are allosterically regulated by the association of eNOS with the Ca^{2+} /calmodulin complex, whereas shear forces can also activate eNOS in the absence of extracellular Ca^{2+} . This overview will attempt to summa-

rize the current state of knowledge and highlight growing points in this major area of NO research.

Shear Forces and the Endothelium

In steady laminar flow the longitudinal shear stress τ acting at any point in the fluid is the product of the shear rate $\dot{\gamma}$ (the velocity gradient) and the coefficient of viscosity μ such that

$$\tau = \mu \dot{\gamma} = \mu \frac{dv}{dy} \quad (1)$$

where v is the local flow velocity and y is distance from the wall. For steady flow in a cylindrical tube the velocity profile is parabolic, and the velocity gradient steepens toward the wall, where the velocity of the fluid is zero if there is no slip (Fig. 1). Shear stress is consequently greatest at the wall and is given by

$$\tau = \frac{4\mu\dot{Q}}{\pi r^3} = \frac{4\mu v_{\text{mean}}}{r} \quad (2)$$

where \dot{Q} is the volumetric flow rate, r is the tube radius, and v_{mean} is the mean flow velocity. *In vivo*, the time-averaged shear forces experienced by the endothelium of conduit arteries are of the order of 10–30 dynes/cm², but in venules and veins they may be as low as 1–6 dynes/cm² (Olesen *et al.*, 1988; Taber, 1998). In arterioles >20 μm in size, estimates are comparable with large arteries, and in the smallest arterioles and capillaries levels may be as high as 100 dynes/cm² (Pries *et al.*, 1995). Since NO production increases monotonically with time-averaged shear stress until it approaches a plateau at 10–30 dynes/cm (Fig. 2) (Hecker *et al.*, 1993; Hutcheson and Griffith, 1994; Posch *et al.*, 1999), basal NO release (Griffith *et al.*, 1984; Martin *et al.*, 1986) will be continuously amplified by blood flow, thus explaining the often large (up to 30%) increases in systemic pressure that follow inhibition of NO production *in vivo* (see Moncada *et al.*, 1991 for review). Shear stress also stimulates endothelial uptake of L-arginine, the physiological substrate for eNOS, by increasing the velocity but not the affinity of the L-arginine transport system, thereby enhancing NO production (Posch *et al.*, 1999).

Influence of Flow

Equation (2) implies that NO release will be sensitive to flow velocity, blood viscosity, and alterations in vascular caliber, but under physiological conditions it may be difficult to discriminate between the effects of changes in these interdependent parameters. Arguably, however, acute changes in flow are the most important physiological determinant of changes in endothelial shear stress (Fig. 1). Flow-induced NO release and dilation have been demonstrated in conduit arteries (Pohl *et al.*, 1986; Rubanyi *et al.*, 1986), resistance arteries (Griffith *et al.*, 1987, 1990a; Pohl *et al.*, 1991), and

Figure 1 Elevations in arterial flow rate ($\dot{Q}_2 > \dot{Q}_1$) increase endothelial shear stress (τ), the principal hemodynamic stimulus to the endothelium, resulting in NO release and an increase in vascular caliber that restores τ back toward baseline. Shear stress also promotes NO release from venules, from which it diffuses and dilates adjacent arterioles, thereby permitting cross talk between the inflow and outflow of blood. Endothelium-derived NO inhibits sympathetic nerves (SYMP) that promote constriction, and in some vessels NO is itself released from nonadrenergic noncholinergic (NANC) nerves. Prostanoids such as prostacyclin (PGI₂) may also contribute to flow-dependent dilation, but a flow-dependent role for endothelium-derived hyperpolarizing factor (EDHF) remains to be demonstrated.

arterioles (Kuo *et al.*, 1990, 1991) from a wide variety of vascular beds. The response is well suited to respond to changes in organ function on a dynamic basis, as it is activated within seconds and maximal within 1 to 2 min. NO may also participate in the regulation of flow on subacute time scales. For example, perfusion of a segment of rabbit central ear artery isolated between two ligatures increases to ~50% of its preocclusion control level over 90 min as a consequence of slow NO-dependent diversion of flow through preexisting collateral pathways (Randall and Griffith, 1992). NO-mediated, flow-dependent dilatation has been demonstrated in isolated venules (Kuo *et al.*, 1993; Koller *et al.*, 1998), and the associated diffusion of NO to nearby arterioles may contribute to the coordination of tissue perfusion. Increases in venular flow velocity have thus been shown to promote arteriolar dilation in the skeletal muscle microvasculature via this mechanism (Boegehold, 1996).

Equation (2) defines shear stress for steady laminar flow, but physiological NO release is also highly sensitive to flow pulsatility (Pohl *et al.*, 1986), being maximal at a similar pulse frequency of 5 Hz in conduit arteries from the rabbit, rat, and pig (Fig. 2) (Griffith *et al.*, 1991a; Hutcheson and Griffith, 1991, 1994). Vascular caliber consequently increases if steady flow becomes pulsatile at the same mean flow rate in an NO-dependent fashion (Shimoda *et al.*, 1998). In the isolated rabbit heart, NO release is enhanced by the periodic compression imposed by contraction (Lamontagne *et al.*, 1992), and in conscious dogs epicardial coronary dilation in response to changes in pacing frequency is mediated by NO (Canty and Schwartz, 1994). Changes in heart rate may thus directly modulate organ perfusion via the endothelium.

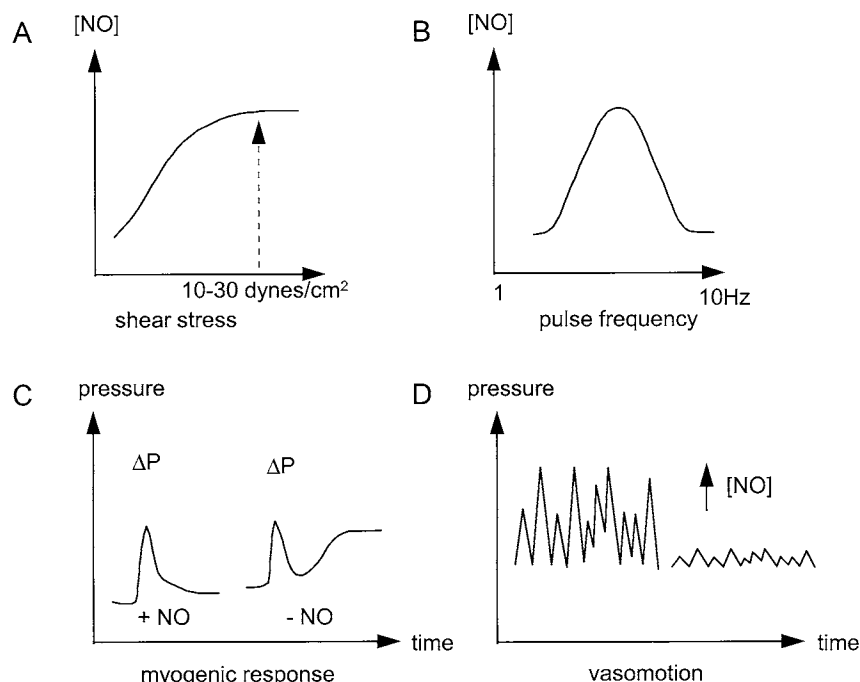

Figure 2 Key mechanisms involved in the regulation of perfusion by NO. (A) Endothelial NO production increases monotonically with time-averaged shear stress, reaching a plateau at 10 to 30 dynes/cm². (B) NO release from the endothelium is sensitive to flow pulsatility, being maximal at pulse frequencies of ~5 Hz. (C) In isolated vessels acute increases in transmural pressure (ΔP) promote a myogenic constrictor response, normally attenuated by NO. Loss of NO activity also elevates basal constrictor tone. (D) The amplitude of spontaneous oscillations in vascular caliber (vasomotion) is damped by NO.

Another way in which flow may influence NO production is through the release of agonists such as ACh, ATP, bradykinin, and substance P from endothelial cells themselves (Fig. 3) (Milner *et al.*, 1990). In the isolated rat lung, for example, perfusion pressure is elevated by P₂ purinoceptor antagonism, suggesting the participation of flow-dependent release of ATP (Hassessian *et al.*, 1993). The potential clinical importance of such autocrine mechanisms has been confirmed in the human myocardium, in which bradykinin B₂ antagonists promote constriction and reduce basal flow (Groves *et al.*, 1995), and in the human forearm, in which flow-dependent dilation is enhanced by angiotensin-converting enzyme (ACE) inhibitors that decrease the metabolism of bradykinin (Hornig *et al.*, 1997). As ATP and bradykinin are rapidly degraded by ectoenzymes, their delivery to receptors will be governed by diffusive and convective mass transport processes in the intimal hydrodynamic boundary layer. Dull and co-workers (1992) thus demonstrated that a stepwise increment in flow produced rapid elevations in endothelial [Ca²⁺]_i that decayed over minutes in the presence of either ATP or its nonhydrolysable analog ADP β S, but that additional increases in flow evoked further Ca²⁺ transients only in the presence of ATP. This is consistent with rapid equilibration of boundary layer and bulk concentrations of ADP β S, but not ATP, because of dynamic clearance by the 5'-nucleotidase.

In contrast to the effects of flow, NO release from conduit arteries is depressed by acute increases in mean transmural pressure (Rubanyi, 1988) and is inversely related to the amplitude of the pressure pulse during pulsatile flow (Hutcherson and Griffith, 1991). Agonist-stimulated NO release from cultured endothelial cells grown on a flat surface also appears to be susceptible to the effects of pressure, exhibiting a progressive but reversible ~sixfold decrease over the range 0–160 mm Hg (Hishikawa *et al.*, 1992), whereas NO release from cells grown on microcarrier beads was found to be insensitive to changes in pressure (Kelm *et al.*, 1991). Because the direct effects of pressure on NO release are quantitatively smaller than those of flow, they are likely to be of less physiological importance. Indeed, in a study of 500 clinically fit adults, no correlation was found between mean blood pressure and the magnitude of flow-dependent dilation measured ultrasonically in the brachial or femoral arteries following release of distal limb occlusion (Celermajer *et al.*, 1994).

Influence of Constrictor Tone

The second factor determining shear stress is vascular diameter. For a given flow rate, shear forces are necessarily lower when diameter is greater, so that local constrictor mechanisms may exert an important influence on NO re-

Figure 3 Pathways involved in the activation of eNOS by shear forces. G protein–phospholipase C interactions that involve tyrosine kinase (TK)-dependent phosphorylation result in transient IP_3 (IP_3)-evoked Ca^{2+} release from internal stores. The subsequent depletion of stores then promotes influx of Ca^{2+} via a store-operated channel (SOC) that appears to be activated by mechanisms involving TK-dependent phosphorylation and epoxyeicosatrienoic acids (EETs) derived from arachidonic acid via the cytochrome P-450 monooxygenase (CYP_{450}). Shear stress and elevations in $[\text{Ca}^{2+}]_i$ also stimulate K^+ channel activity, and the associated decrease in membrane potential (V_m) promotes Ca^{2+} entry by increasing the electrochemical gradient for influx. Elevations in $[\text{Ca}^{2+}]_i$ activate the Ca^{2+} /calmodulin (CM)-dependent eNOS that is located in membrane caveolae, where it is negatively regulated by the structural coat protein caveolin (inset). TK-dependent phosphorylation and G proteins may stimulate phosphatidylinositol 3-kinase (PI3K), which is an upstream activator of protein kinase B (Akt/PKB) that in turn phosphorylates eNOS to increase its activity in a Ca^{2+} -independent fashion in response to fluid shear stress. Shear forces may also increase NO production by releasing endothelium-dependent agonists such as ATP, bradykinin, and substance P.

lease. *In vivo*, ambient vascular tone is largely determined by the intrinsic myogenic behavior of smooth muscle, with a contribution from sympathetically mediated constriction. Increases in local transmural pressure lead to constriction (and decreases in pressure to dilation) through the ability of vascular smooth muscle to sense and respond to changes in circumferential wall stress—the so-called myogenic response (Fig. 2) (for review, see Davis and Hill, 1999). In isolated perfused vessels, myogenic tone is potentiated by endothelial denudation and attenuated by basal NO release, the inhibitory role of the endothelium predictably being greater in the presence of shear stress, such that myogenic constriction is most pronounced at low flow rates and attenuated by up to ~50% as flow is increased (Griffith and Edwards, 1990a; Pohl *et al.*, 1991; Kuo *et al.*, 1991; Sun *et al.*, 1995a; Juncos *et al.*, 1995). In the converse sense, flow-dependent dilation is maximal at transmural pressures equivalent to those found under normal physiological conditions

when myogenic tone is at an intermediate level (Kuo *et al.*, 1990, 1991). *In vivo*, eNOS inhibitors tend to unmask or enhance myogenic constriction in large arterioles that normally react little to increases in pressure, either having little effect on smaller downstream arterioles, or causing them to dilate as compensatory mechanisms may be activated by upstream constriction (Hester *et al.*, 1993; Jones *et al.*, 1995). Loss of NO activity thus causes a shift in the major site of vascular resistance upstream to vessels which are less tightly controlled by metabolites.

Theoretically, the myogenic response and flow-dependent dilation may be considered positive feedback mechanisms, with high pressure promoting progressively greater constriction and flow-dependent dilation further enhancing flow if the supply pressure remains unchanged. However, myogenic constriction will increase shear stress, thereby promoting NO release that opposes the initial constrictor stimulus and confers circulatory stability. Sympathetically mediated con-

striction will similarly increase endothelial shear stress and NO production, but in addition to directly decreasing smooth muscle tone, NO exerts an inhibitory prejunctional effect on catecholamine release, thereby contributing to a negative feedback loop that diminishes the original constrictor stimulus (Fig. 1) (Teschamariam and Cohen, 1988). Pressure-dependent, neurogenic, and flow-dependent control mechanisms may thus coexist in a state of dynamic equilibrium.

Adventitial nerves may themselves attenuate constrictor tone through NO-dependent mechanisms (Fig. 1). For example, NO is synthesized by nonadrenergic, noncholinergic (NANC) nerves in the corpus cavernosum, thereby mediating penile erection (Rajfer *et al.*, 1992). A similar mechanism contributes to dilatation in cerebral and mesenteric arteries (Toda and Okamura, 1990; Ahlner *et al.*, 1991). It has also been suggested that acetylcholine (ACh) released from parasympathetic adventitial nerves diffuses to the endothelium and stimulates NO synthesis, on the basis that vasodilatation induced by vagal stimulation is blocked by atropine and eNOS inhibitors (Brotten *et al.*, 1992; McMahon *et al.*, 1992). In analogous fashion, neurotransmitter peptides such as vasoactive intestinal polypeptide (VIP) and substance P mediate endothelium-dependent vasodilatation in salivary gland and skeletal muscle (Persson *et al.*, 1991; Edwards and Garrett, 1993).

Influence of Viscosity

The third factor determining shear stress is viscosity, whose importance in the regulation of NO production has been confirmed by the demonstration that solutions containing high-molecular-weight dextran enhance NO release from isolated vessels through a mechanism that is independent of flow rate (Teschamariam and Cohen, 1988; Hutcheson and Griffith, 1991). Dextran has also been shown to evoke NO-dependent increases in arteriolar diameter in the microcirculation *in vivo* (de Wit *et al.*, 1997). These observations suggest that the hemodynamic stimulus to the endothelium is shear stress, rather than flow velocity. Indeed, Ando and colleagues (1993) found that elevations in $[Ca^{2+}]_i$ evoked by flow are amplified by increased perfusate viscosity, but that their magnitude correlates with absolute shear stress ($\tau = \mu \times \dot{\gamma}$), rather than viscosity, μ , or shear rate, $\dot{\gamma}$, when these factors were manipulated separately. Viscosity-related increases in NO production are likely to contribute to the increased organ blood flow found in high viscosity states such as polycythemia (Wilcox *et al.*, 1993).

NO and Cardiovascular Optimization

Pressure Gradients

Flow, resistance, and the pressure gradient driving flow (i.e., pressure drop per unit length) in a cylindrical tube of length L and radius r under steady laminar conditions are related according to the Poiseuille equation

$$\frac{dP}{dL} = \frac{(P_1 - P_2)}{L} = \frac{8 \mu \dot{Q}}{\pi r^4} = R \times \dot{Q} \quad (3)$$

where P_1 and P_2 are the supply and output pressures, respectively, and R denotes hydraulic resistance. It is readily appreciated from this formula that if the vascular tree consisted simply of a system of rigid tubes, left ventricular pressure would need to rise to physiologically unacceptable levels to sustain the approximately fivefold increase in cardiac output that occurs during maximal exercise. In practice, however, flow-dependent dilation can readily restore the pressure gradient, dP/dL , toward its control value because of the fourth power dependence on radius but direct relationship with flow. This ability to stabilize pressure gradients has been confirmed experimentally in the rat saphenous artery, in which the pressure drop remains virtually unchanged over a fivefold range of flow rates if the endothelium is intact (Khayutin *et al.*, 1993a,b). Calculations suggest that in the rabbit ear, the pressure gradient driving flow asymptotically approaches a constant value at high flow rates in arterial branch generations with diameters ranging from 70 to 800 μm as a direct consequence of NO release (Griffith *et al.*, 1987). In human conduit arteries flow-dependent dilation can vary between 5 and 15% of control diameter and could thus in theory accommodate up to an $\sim 60\%$ increase in flow with no change in pressure gradient (Celermajer *et al.*, 1994). However, small resistance arteries and arterioles may be considerably more sensitive to changes in flow. Mesenteric and coronary arterioles have thus been shown to exhibit increases in diameter in response to increments in flow of $\sim 70\%$ and $\sim 30\%$, respectively (Smiesko *et al.*, 1989; Kuo *et al.*, 1990). Since small vessels are the major site of systemic resistance, this is likely to explain why mean arterial pressure increases by only 10–20% during maximal exercise.

Stabilization of pressure gradients by the endothelium may confer other physiological advantages. First, it will contribute to hydraulic efficiency, particularly in the microcirculation where flow is viscous rather than inertial. Energy losses are directly proportional to the product of pressure gradient and flow and therefore are proportional to \dot{Q} if flow-dependent dilation maintains a constant pressure gradient, rather than to \dot{Q}^2 as in a rigid tube (Griffith *et al.*, 1987). During maximal exercise, for example, this would represent a fivefold reduction in hydraulic energy expenditure. Second, stabilization of pressure gradients will help to prevent a microvascular “steal” phenomenon that would otherwise result from the release of vasodilator metabolites. Metabolic dilation will cause a local fall in resistance and an increase in flow. Consequently, if the supply pressure remains constant [P_1 in Eq. (3)] and if the resistance of proximal feed arteries remains fixed, Poiseuille’s law implies that there will be a fall in distal pressure [P_2 in Eq. (3)] which could decrease the perfusion of adjacent tissue elements. A steal effect will nevertheless be offset by the upstream dilation of proximal arterioles and distributive arteries through both myogenic and flow-dependent mechanisms, thereby normalizing distal pressures. This will have obvious benefits in

terms of the delivery of oxygen and nutrients, as well as contributing to the physiological regulation of hydrostatic pressure and microcirculatory fluid exchange. Direct visualization of the microcirculation of the rabbit ear also suggests that NO importantly helps to maintain spatially homogeneous patterns of flow distribution by preserving similar relative resistances in different vascular segments under altered conditions of flow and constriction (Griffith *et al.*, 1987).

Relationship between “Constant” Shear Stress and Minimization of Hydraulic Work

Although there may be an approximately tenfold difference in shear stress between the arterial and venous circulations, there is a surprising similarity in its magnitude across species and vessel size given that flow rates in different vessels may vary by a factor of $\sim 10^4$ (Pries *et al.*, 1995; Taber, 1998). Furthermore, long-term increases or decreases in flow over days or weeks result in adaptations of local arterial caliber through a strictly endothelium-dependent mechanism that restores shear stress to its previous control level (Langille and O'Donnell, 1986; Tronc *et al.*, 1996). A simple theoretical approach devised by Murray (1926) provides insights into the design principles that could underlie these observations. Murray postulated that the sum of the work and energy losses incurred through viscous friction and through maintaining a finite circulatory volume ought in theory to be as small as possible for optimum economy. For an artery of unit length, total energy losses, W , can be written as

$$W = \frac{8 \mu \dot{Q}^2}{\pi r^4} + b r^2 \quad (4)$$

where b is a constant reflecting the metabolic cost of blood. It can readily be shown that there is a minimum in this combined term (i.e., $dW/dr = 0$) when $\dot{Q} \propto r^x$, where the exponent $x = 3$. One immediate theoretical corollary of this result is that shear stress, which is proportional to \dot{Q}/r^3 [Eq. (2)], should be constant throughout the circulation. Values of x close to 3 have been obtained for arteries in the dog lung and in the human cerebral and coronary circulations, and for arterioles in the rat microcirculation (Hutchins *et al.*, 1976; Mayrovitz and Roy, 1983; Liu and Ritman, 1986; Rossitti and Löfgren, 1993). In the rabbit ear median values of x remain close to the Murray optimum over an approximately tenfold range of flow rates at bifurcations of arteries with a wide range of diameters, provided that there is normal NO activity (Griffith and Edwards, 1990b). High levels of pharmacological constriction cause deviation from the optimum, but x may be restored toward 3 by agonists that dilate via the endothelium (Griffith *et al.*, 1991b). Adaptive control mechanisms also restore optimality in the sense postulated by Murray in the human retinal circulation following chronic reductions in flow caused by head trauma (Rossitti and Frisen, 1994).

Murray's hypothesis is clearly a simplification of the physiological situation, as it ignores the pulsatile nature of blood flow and the non-Newtonian properties of blood. Furthermore, there may be a relatively broad statistical spread

in the values of x obtained experimentally; in the rabbit ear microvasculature, for example, the frequency distribution of the exponent x is skewed to the right with a significant number of estimates ≥ 3 (Griffith and Edwards, 1990b). Calculations nevertheless show that the mathematical optimum is “shallow,” in that the energetic cost penalty incurred by departing from $x = 3$ is only a few percent over a wide range of exponents ($x = 1$ to 10) (Sherman *et al.*, 1989). Although the agreement between experimental data and theory is approximate rather than exact, it is nevertheless consistent with the view that flow-dependent dilation contributes to cardiovascular design by optimizing tissue perfusion for a given level of cardiac work and finite blood volume. A simple modification of Eq. (4) incorporating an extra term to take into account the energy expended in maintaining the vessel wall in an active state of myogenic constriction has predicted that average shear stress will be correlated with ambient pressure at different levels of the circulation, and will therefore be lowest in veins (Taber, 1998).

Interactions of NO with Other Dynamic Control Mechanisms

CONDUCTED RESPONSES

Localized dilator responses, including those induced by ACh, can propagate electrotonically along the arterial wall with a velocity and amplitude space constant similar to that in other tissues (Segal *et al.*, 1989; Frame and Sarelius, 1995). The myogenic response also propagates electronically, with the magnitude of the conducted constriction correlating with the locally sensed pressure change (Rivers, 1995). Such conducted responses may interact synergistically with flow-dependent dilation to minimize local perfusion heterogeneity, by integrating the intensity and nature of stimuli arriving from downstream sites. Dilation of a daughter vessel at a branch point will increase flow in the parent vessel, thereby decreasing local pressure and flow through the nondilated daughter branch, but steal effects may be offset by propagation of the dilator response into the nondilated daughter branch (Segal *et al.*, 1989). Much remains to be learned about the interaction between flow-dependent and conducted control mechanisms. Topical application of L-arginine or ACh to distal microvessels, for example, enhances remote upstream propagated responses through an unknown mechanism that is sensitive to inhibition of eNOS (Frame and Sarelius, 1995).

VASOMOTION

Cyclic fluctuations in perfusion with a wide range of frequencies and amplitudes can be observed in myocardial subregions as large as 1 mm³ in size, and at segmental and lobar levels in the pulmonary circulation (Sestier *et al.*, 1978; Glennly *et al.*, 1995). This temporal variability is largely generated by oscillations in vascular diameter, a phenomenon known as vasomotion (Fig. 2). Although the patterns of vasomotion observed in isolated vessels are often highly irregular, they are not random, but rather are generated by

deterministic nonlinear control mechanisms that can be classified as “chaotic” (see Griffith, 1996, for review). In resistance arteries, fluctuations in pressure and flow are generated by a relatively small number of dominant control variables (probably four) and involve nonlinearity in the coupling between two distinct intracellular and membrane Ca^{2+} oscillators located at the level of the smooth muscle cell. Although NO profoundly affects the visible form and amplitude of vasomotion, which can be completely suppressed by micromolar concentrations of ACh (Griffith and Edwards, 1994), nonlinear analysis confirms that the mathematical complexity of vasomotion (assessed as a fractal dimension) is insensitive to changes in pressure, flow, and NO activity (Griffith, 1996). This supports the view that mechanical forces and their influence on NO release do not control the cellular mechanisms that underlie vasomotion in a fundamental dynamical sense (Parthimos *et al.*, 1999). Nevertheless, the response of chaotic systems to perturbation is highly unpredictable, a property that may explain why NO can also “paradoxically” promote rhythmic activity in otherwise quiescent arteries under certain experimental conditions (Jackson *et al.*, 1991).

Vasomotion is thought to limit extravascular fluid filtration by reducing hydrostatic pressure during periods of low flow, to enhance lymphatic drainage through a pumping action, and to represent a beneficial hemodynamic response during hypoxia and ischemia by decreasing local vascular resistance. One implication of the demonstration of nonlinear behavior is that vascular control possesses greater flexibility than is possible in a linear system: in chaotic systems minute perturbations can effect changes in state with minimal energy expenditure, thereby readily permitting escape from patterns of behavior that have become disadvantageous. NO may consequently exert subtle effects on many aspects of microvascular function. Present evidence suggests that NO activity normally suppresses the 0.2–0.6 Hz frequency component of blood pressure variability *in vivo*, and experiments with eNOS knockout mice confirm that this is specifically attributable to NO derived from the endothelium (Nafz *et al.*, 1997; Stauss *et al.*, 1999).

Role of Ca^{2+} in the Activation of eNOS by Shear Forces

Ca^{2+} -Dependent Mechanisms

As discussed elsewhere in this volume, binding of the Ca^{2+} /calmodulin complex to the eNOS dimer is central to its catalytic activity. This interaction is likely to underlie the endothelial response to acute increases in shear stress, as exposure to laminar flow initiates a rise in $[\text{Ca}^{2+}]_i$ within 1 to 3 s, which is followed by NO release within 2 to 3 s (Kanai *et al.*, 1995). Such $[\text{Ca}^{2+}]_i$ transients may be monophasic, biphasic, or oscillatory, and high-resolution imaging has demonstrated elevations in $[\text{Ca}^{2+}]_i$ in distinct nuclear and subplasmalemmal pools, whose magnitude and speed of on-

set are directly related to the shear stress applied (Geiger *et al.*, 1992; Shen *et al.*, 1992; Falcone *et al.*, 1993; Kanai *et al.*, 1995). Some reports suggest preferential elevations in $[\text{Ca}^{2+}]_i$ at the downstream edge of the endothelial cell (Geiger *et al.*, 1992; Falcone *et al.*, 1993), whereas others demonstrate a repetitive Ca^{2+} wave that originates at the upstream edge and propagates downstream (Yoshikawa *et al.*, 1997). Repeat exposure to flow does not always activate the same subpopulation of cells, suggesting the existence of a refractory period (Falcone *et al.*, 1993; James *et al.*, 1995). Theoretical computations based on the irregular surface geometry of endothelial monolayers suggest large cell-to-cell variations in stress fields and an uneven distribution over the surface of individual cells due to their nonuniform thickness (Davies, 1995). This could explain why the number of cells responding to flow increases with the magnitude of the applied shear stress in a graded fashion (Geiger *et al.*, 1992; Falcone *et al.*, 1993; James *et al.*, 1995; Yoshikawa *et al.*, 1997).

The Ca^{2+} -dependent pathways through which shear stress stimulates NO synthesis are similar to those activated by agonists, which transiently (~ 2 min) activate the PLC- γ_1 isoform of phospholipase C via tyrosine phosphorylation, resulting in parallel formation of inositol 1,4,5-trisphosphate (InsP_3) and Ca^{2+} release from the endoplasmic reticulum (ER) (Fleming *et al.*, 1996). Tyrosine phosphorylation of PLC is rapidly reversed by the activation of Ca^{2+} -dependent tyrosine phosphatases, thus explaining the transitory nature of the InsP_3 response (Fleming *et al.*, 1996). Stepwise changes in flow similarly stimulate InsP_3 synthesis, with levels exhibiting a peak at 15–30 s (Nollert *et al.*, 1990; Prasad *et al.*, 1993). Endothelial InsP_3 turnover is also modulated by oscillatory mechanical forces, with both increases and decreases in the frequency of cyclical stretch stimulating a transient rise (Rosales and Sumpio, 1992; Brophy *et al.*, 1993). It is currently unknown if this mechanism contributes to the sensitivity of NO production to flow pulsatility.

After the initial peak in $[\text{Ca}^{2+}]_i$ induced by agonists or stepwise changes in shear, there may be a sustained elevation above baseline which is maintained by influx of extracellular Ca^{2+} . This occurs principally via a “store-operated channel” regulated by the Ca^{2+} status of the ER stores themselves. Indeed, basal NO production is markedly enhanced by depletion of the ER with compounds that inhibit its Ca^{2+} -ATPase pump, such as cyclopiazonic acid (Moritoki *et al.*, 1994), although the mechanism exhibits tachyphylaxis and after prolonged depletion neither agonists nor acute changes in flow elicit NO release (Hutcheson and Griffith, 1997). Only a small subcomponent of the ER is involved in regulating the store-operated channel, because ryanodine, which locks a specific ER Ca^{2+} -activated Ca^{2+} release channel in an open subconductance state, depletes the ER more rapidly than cyclopiazonic acid, but does not activate Ca^{2+} influx (Sasajima *et al.*, 1997). Functional compartmentalization may explain why ryanodine does not significantly modulate shear stress- or ACh-induced NO release in cascade bioassay (Hutcheson and Griffith, 1997).

The mode of activation of the endothelial store-operated channel is controversial, and it is unknown whether it requires direct mechanical coupling with InsP_3 receptors present in the peripheral ER, as suggested in other cell types (Kiselyov *et al.*, 1998). It is established, however, that Ca^{2+} entry via this channel is attenuated by tyrosine kinase inhibitors and prolonged by inhibitors of tyrosine phosphatase, and it may therefore involve a protein tyrosine phosphorylation transduction cascade (Fleming *et al.*, 1996; Davis and Sharma, 1997). Store depletion also promotes the synthesis from arachidonic acid of epoxyeicosatrienoic acids (EETs), which may function as a “ Ca^{2+} influx factor” that promotes Ca^{2+} entry (Graier *et al.*, 1995; Hoebel *et al.*, 1997; Rzigalinski *et al.*, 1999). These microsomal P-450 monooxygenase metabolites activate tyrosine kinase in endothelial cell homogenates (Hoebel *et al.*, 1998) and can directly stimulate NO synthesis in intact arteries (Tan *et al.*, 1997; Hutcheson *et al.*, 1999). The rate at which Ca^{2+} is sequestered within stores by the ER Ca^{2+} -ATPase pump also influences NO production, as agonist-induced relaxations are attenuated in phospholamban gene-ablated mice in which there is enhanced uptake by the ER (Sutliff *et al.*, 1999).

In marked contrast to vascular smooth muscle, the endothelium is devoid of voltage-operated Ca^{2+} channels, and membrane hyperpolarization promotes, rather than inhibits, Ca^{2+} entry by increasing the electrochemical gradient for Ca^{2+} influx (Lückhoff and Busse, 1990). Agonists may stimulate endothelial hyperpolarization by increasing the open-state probability of Ca^{2+} -activated K^+ (K_{Ca}) channels following elevations in $[\text{Ca}^{2+}]_i$, a mechanism that may consequently be closely coupled with store depletion and subsequent Ca^{2+} influx (Davis and Sharma, 1997). EETs may amplify this hyperpolarization as they activate K_{Ca} channels (Graier *et al.*, 1995; Hoebel *et al.*, 1997). Several studies have confirmed that K^+ channel activation may contribute to NO release stimulated both by increases in time-averaged shear stress and by the frequency-related component of pulsatile flow, with subtypes involved including high-, medium-, and low-conductance K_{Ca} channels and ATP-sensitive K^+ channels (Ohno *et al.*, 1993; Hutcheson and Griffith, 1994). Flow also activates an inwardly rectifying K^+ channel that mediates hyperpolarization and is fully activated at physiological levels of shear stress, desensitizes slowly, and recovers rapidly on cessation of flow (Olesen *et al.*, 1988). However, when such channels are enclosed by a micropipette within a cell-attached patch, they respond to flow after a delay of several minutes, thus implying that gating does not require direct exposure to shear stress (Jacobs *et al.*, 1995). In cultured endothelial cells K^+ channel activity and membrane potential may not always be coupled to NO release stimulated by shear stress or agonists (O'Neill, 1995; Gooch and Frangos, 1996).

Ca^{2+} -Independent Mechanisms

Shear stress may also enhance the catalytic activity of eNOS through a Ca^{2+} -independent mechanism that is dis-

tinct from the effects of agonists. During the initial phase of exposure of cultured endothelium to flow, NO production exhibits mixed Ca^{2+} dependence and Ca^{2+} independence, but over time eNOS activity becomes Ca^{2+} /calmodulin independent while nevertheless permitting continuous production of NO (Kuchan and Frangos, 1994; O'Neill, 1995). This Ca^{2+} -independent NO production requires tyrosine phosphorylation of eNOS or an associated regulatory protein, and it can therefore be attenuated by tyrosine kinase inhibitors and be mimicked by protein tyrosine phosphatase inhibitors, which induce sustained NO release in the absence of extracellular Ca^{2+} (García-Cardena *et al.*, 1996; Fleming *et al.*, 1996, 1998). Following exposure to shear stress, eNOS is also rapidly phosphorylated on serine residues (Corson *et al.*, 1996; Fleming *et al.*, 1998). Although serine phosphorylation at specific positions, for example, by protein kinase C, may be inhibitory (Hirata *et al.*, 1995), more recent studies have shown that shear stress increases the catalytic activity of eNOS in a Ca^{2+} -independent fashion following serine phosphorylation by the serine/threonine kinase Akt (protein kinase B) (Fulton *et al.*, 1999; Dimmeler *et al.*, 1999). Activation of Akt is downstream of phosphatidylinositol 3-kinase (PI3K), as increases in NO production are abolished by the PI3K inhibitor wortmannin (Fulton *et al.*, 1999; Dimmeler *et al.*, 1999). Agonists and shear stress also cause eNOS to associate with the heat-shock protein Hsp 90 (García-Cardena *et al.*, 1998). This molecular chaperone regulates protein folding, and its recruitment to eNOS results in an increase in activity that may be effected by allosteric modulation or stabilization of the eNOS dimer in a Ca^{2+} /calmodulin-independent fashion.

How Are Shear Forces Sensed?

Fluid shear stress stimulates membrane mechanoreceptors that subsequently lead to the activation of a wide spectrum of intracellular signaling pathways (Fig. 3). In the context of eNOS, the physical structure and fluidity of the endothelial cell membrane are both important determinants of the transduction of shear forces, since cleavage of sialic acid residues from the endothelial cell glycocalyx with neuraminidase and “stiffening” of the endothelial cell membrane with cholesteryl hemisuccinate selectively impair flow—but not agonist-induced NO synthesis (Hecker *et al.*, 1993; Knudsen and Frangos, 1997). As discussed above, ion channels are also activated by shear stress, but none has convincingly emerged as the primary mechanosensor coupled to NO production. Indeed, a more likely scenario is that the modulation of transmembrane Ca^{2+} and K^+ fluxes by increases in flow is secondary to the activation of a highly complex network of signaling mechanisms.

G Proteins

Activation of endothelial PLC by agonists involves G proteins coupled to the NO synthetic pathway that include a

pertussis toxin (PTX)-sensitive G_i protein linked to serotonergic, α_2 -adrenergic, and muscarinic receptors, and a PTX-insensitive G_q protein linked to bradykinin and ATP receptors (Boulanger and Vanhoutte, 1997). G proteins also participate in the earliest transduction events associated with flow, as immunoprecipitation techniques demonstrate activation of heterotrimeric G-protein subunits within 1 s of exposure to shear stress (Gudi *et al.*, 1996), and G_i and G_q subtypes have both been reported to contribute to the NO response to flow (Kuchan *et al.*, 1994). Comparison of step, ramp, and impulse changes in flow on NO production suggests the existence of a rapid G-protein-dependent response that is sensitive to the rate of change of shear stress and a G-protein-independent response to steady shear forces (Frangos *et al.*, 1996). The general G-protein inhibitor GDP β S thus blocks NO production during the first hour of exposure of cultured human umbilical vein endothelial cells (HUVECs) to flow, but significant attenuation is no longer apparent after 1 hour (Kuchan *et al.*, 1994). Membrane fluidity may be an important determinant of the protein receptor-independent GTPase activity of G proteins reconstituted into phospholipid vesicles and subjected to shear stress (Sivaramaprasad *et al.*, 1998). Liposomes containing lysophosphatidylcholine or treated with benzyl alcohol to increase bilayer fluidity exhibit substantial enhancement of basal GTPase activity, whereas incorporation of cholesterol has the opposite effect.

Caveolae

Cholesterol-rich invaginations of the endothelial cell membrane known as caveolae serve as specialized signaling domains whose particular structural properties confer sensitivity to membrane tension and allow the rapid transduction of mechanical forces into biochemical events (Fig. 3). Uniquely among the NOS isoforms, eNOS possesses a substrate site for acyl transferase at its amino terminus that permits sequential N-myristoylation and palmitoylation and subcellular localization within caveolae and in the region of the Golgi apparatus (Robinson and Michel, 1995; Liu *et al.*, 1996). Caveolin-1, the key structural coat protein of caveolae in endothelial cells, interacts with eNOS to form an inactive heteromeric complex that is quantitatively dissociated by Ca^{2+} /calmodulin, leading to NO production (Michel *et al.*, 1997; Ju *et al.*, 1997). Acute changes in flow cause rapid dissociation of eNOS from caveolin and binding to calmodulin, high levels of which are also found in caveolae (Rizzo *et al.*, 1998a).

Other signaling molecules involved in the response to shear forces—including G proteins, PLC, and tyrosine kinases—are also localized in caveolae (Shaul and Anderson, 1998). Shear stress rapidly activates members of the Src tyrosine kinase family (Takahashi and Berk, 1996), and a wide spectrum of caveolar proteins become tyrosine phosphorylated following acute increases in flow (Rizzo *et al.*, 1998b). The same proteins are also phosphorylated following stimulation by agonists (Liu *et al.*, 1997), suggesting

the existence of common pathways for receptor- and shear-mediated events, although a greater fraction of the caveolae present in subcellular fractions respond to flow than agonists (Rizzo *et al.*, 1998b). More recent evidence suggests that colocalization of eNOS with an upstream activator of protein kinase B (Akt/PKB) in the cell membrane is obligatory for Ca^{2+} -independent synthesis of NO (Fulton *et al.*, 1999). Its upstream activator PI3K is found in caveolae (Liu *et al.*, 1997) and is regulated by caveolar signaling proteins that are sensitive to shear stress, including G proteins, Ras, and Src-family tyrosine kinases (Katada *et al.*, 1999; Shepherd *et al.*, 1998).

Cytoskeleton and Integrins

The cytoskeleton is supported by actin in its polymeric or filamentous (F-actin) form, which is organized into microfilament bundles that confer tension to the cell and a lattice of microtubules formed by polymerization of tubulin; which in conjunction with intermediate filaments, provides cell rigidity (Davies, 1995; Banes *et al.*, 1995). In rabbit aorta, endothelial NO release evoked by acute changes in shear stress is attenuated by cytochalasin B (an F-actin depolymerizing agent), phalloidin (an F-actin stabilizing agent), and colchicine (an inhibitor of tubulin dimerization), whereas none of these agents affects the response to ACh (Hutcheson and Griffith, 1996). Nocodazole, an agent that interferes with microtubule polymerization, similarly attenuates flow-dependent dilation in isolated skeletal muscle arterioles, without affecting the response to ACh (Sun *et al.*, 1995b), and in mice lacking vimentin, a major intermediate filament protein, NO-mediated flow-dependent dilation is impaired in mesenteric resistance arteries (Henrion *et al.*, 1997). Cytochalasins also prevent the rise in $[Ca^{2+}]_i$ evoked by direct mechanical perturbation of the endothelial membrane (Diamond *et al.*, 1994). By contrast, in cultured endothelial cells neither disruption nor stabilization of actin microfilaments affect the NO response to shear stress or bradykinin, and disruption of microtubules may actually enhance the response to shear (Knudsen and Frangos, 1997). Shear-induced elevations in $[Ca^{2+}]_i$ are unaffected by pharmacological dissolution or stabilization of the microtubule network in cultured cells (Malek *et al.*, 1999). It remains to be determined whether these apparently conflicting findings reflect differences in cellular architecture resulting from culture in the absence of flow, for endothelial cells then lack stress fibers formed from actin microfilaments and an organized lattice of microtubules and intermediate filaments (Davies, 1995; Banes *et al.*, 1995).

The cytoskeleton interacts with other elements that are involved in the sensing of shear stress, perhaps allowing them to function as an integrated dynamic unit. Cytoskeletal components are linked to stretch-activated ion channels, G proteins, and $InsP_3$ -sensitive stores (Banes *et al.*, 1995). They are also involved in the maintenance of caveolae, with caveolin normally undergoing microtubule-dependent cycling between the plasma membrane and the Golgi (Conrad

et al., 1995). Microtubular disruption thus causes accumulation of caveolin in the ER/Golgi intermediate compartment (Conrad *et al.*, 1995), whereas disruption of actin microfilaments causes caveolae to aggregate (Fujimoto *et al.*, 1995). Importantly, physical forces acting on the endothelial cell surface are transmitted via the cytoskeleton to integrins, which are heterodimeric transmembrane glycoproteins that bind to the extracellular matrix on the abluminal side of the cell (Davies, 1995). At such sites of endothelial anchorage there are focal adhesion complexes that contain tyrosine kinases which are rapidly activated by shear stress, including Src (Hamasaki *et al.*, 1996; Takahashi and Berk, 1996). In isolated coronary arterioles in which NO-mediated flow-dependent dilation involves tyrosine kinase-mediated protein phosphorylation, dilatations evoked by flow are attenuated by a blocking antibody targeted at the integrin β_3 chain and by a peptide containing an RGD sequence that specifically inhibits integrin binding to matrix proteins (Muller *et al.*, 1997). This peptide attenuates the endothelial response to flow but does not affect endothelium-dependent relaxations to agonists (Muller *et al.*, 1997). Focal adhesion complexes may therefore be involved in the activation of eNOS by shear forces, although the downstream transduction pathways are presently unknown.

NO-Independent Mechanisms of Endothelial Control

Prostanoids

In some vessels endothelium-derived prostanoids may also contribute to flow-dependent dilation (e.g., Koller and Kaley, 1990a; Friebe *et al.*, 1995), although this is by no means a universal finding (e.g., Holtz *et al.*, 1984; Kuo *et al.*, 1991). Synthesis of prostacyclin, like that of NO, is enhanced both by increases in laminar shear stress and by pulsatile flow through a G-protein-dependent pathway (Pohl *et al.*, 1986; Berthiaume and Frangos, 1992; Onohara *et al.*, 1991). In skeletal muscle arterioles of wild-type mice, NO and prostanoids contribute to flow-dependent dilation to an approximately equal extent, whereas in eNOS knockouts the magnitude of the phenomenon, though attributable entirely to prostanoids, is unchanged because this pathway is upregulated (Sun *et al.*, 1999). There is growing evidence for interactions between the two mediators. Generation of the superoxide anion ($O_2^{\cdot-}$) by cyclooxygenase may thus attenuate functional NO activity (Tsefamariam and Cohen, 1992), whereas the peroxynitrite ion, $ONOO^-$, formed by the combination of these radicals directly stimulates prostaglandin H synthase (Goodwin *et al.*, 1999). The latter mechanism could explain why prostacyclin synthesis by cultured endothelial cells exposed to shear stresses of 25 dynes/cm² is attenuated by ~50% following inhibition of eNOS (Wang and Diamond, 1997). In some models, however, $ONOO^-$ inhibits prostacyclin synthase by causing tyrosine nitration, leaving unmetabolized prostaglandin H_2 to promote vasoconstriction (Zou and Bachschmid, 1999).

EDHF and Gap Junctional Communication

An endothelium-derived hyperpolarizing factor (EDHF) is widely recognized as mediating endothelium-dependent vascular relaxations that are independent of NO and prostanoïd synthesis (see Mombouli and Vanhoutte, 1997 for review). There is now compelling evidence that this agent preferentially diffuses from the endothelium to smooth muscle via myoendothelial gap junctions (Chaytor *et al.*, 1998). Chemical signals may also transfer via gap junctions in the opposite direction from smooth muscle to endothelium, as arteriolar constriction by agonists or high extracellular $[K^+]$ may cause secondary elevations in endothelial $[Ca^{2+}]_i$ and thereby stimulate NO production (Dora *et al.*, 1997). Gap junctions consist of two hemichannels contributed by opposing cells, each formed by six connexin protein subunits arranged around a central pore that permits electrical continuity and intercellular transfer of molecules <1 kDa in size. EDHF-type relaxations and hyperpolarizations are markedly attenuated by inhibitory synthetic peptides that possess sequence homology with regions of the extracellular loops of connexins found in the vascular wall (Chaytor *et al.*, 1998; Hutcheson *et al.*, 1999; Dora *et al.*, 1999), and also by 18 α - and 18 β -glycyrrhetic acids, which are lipophilic aglycones that disrupt gap junctional communication (Taylor *et al.*, 1998; Yamamoto *et al.*, 1999). EDHF-type responses are initiated by mobilization of arachidonic acid by a Ca^{2+} -dependent phospholipase A_2 , but the mechanisms involved distal to this step have not been resolved (Hutcheson *et al.*, 1999). Mediators proposed to be EDHFs include arachidonic acid metabolites such as the endocannabinoid anandamide and epoxyeicosatrienoic acids (EETs) (see Randall and Kendall, 1998 and Campbell and Harder, 1999, for reviews). However, anandamide and EETs can stimulate endothelium-dependent relaxations that involve myoendothelial gap junctions and/or NO, thus questioning their equivalence with EDHF (Hutcheson *et al.*, 1999; Tan *et al.*, 1997; Chaytor *et al.*, 1999).

Transfer of EDHF via gap junctions may explain the difficulty experienced in detecting downstream relaxations mediated by EDHF in cascade bioassay (Mombouli and Vanhoutte, 1997), though under some conditions there may be a small "overspill" of EDHF from intact vessels. The Ca^{2+} ionophore A23187 thus promotes release of EDHF directly into the extracellular space (Hutcheson *et al.*, 1999). In cascade bioassay it is also possible to detect transient hyperpolarization of vascular myocytes under conditions of combined eNOS and cyclooxygenase blockade (Popp *et al.*, 1996). Increases in transmural pressure in the donor vessel enhance the duration but not the amplitude of this downstream hyperpolarizing response, suggesting that mechanical forces modulate EDHF release (Popp *et al.*, 1996). It nevertheless remains to be established whether shear forces activate EDHF/gap junction-dependent mechanisms, a possibility suggested by NO- and prostanoid-independent flow-dependent dilation of cat femoral and rat basilar arteries (Fujii *et al.*, 1991; Melkumyants *et al.*, 1992). Although

endothelium-dependent agonists and shear stress induce endothelial hyperpolarization directly (Olesen *et al.*, 1988; Mehrke and Daut, 1990), there is as yet little evidence that electrotonic transmission of a hyperpolarizing electrical current from the endothelium to smooth muscle contributes significantly to EDHF-mediated responses, perhaps reflecting the relatively small mass of the endothelium relative to the medium (Beny, 1999).

EDHF-type relaxations are particularly prominent in small arteries, including those obtained from the human myocardium, as might be expected when the average diffusion distance for a chemical mediator within the media is small and the endothelial:smooth muscle cell ratio is high (Berman and Griffith, 1998; Miura *et al.*, 1999). Gap junctional communication may accordingly be particularly important in the regulation of microcirculatory flow. In the rabbit central ear artery, experiments with connexinmimetic peptides have shown that NO-dependent relaxations dominate the response to ACh, whereas the gap junctional component dominates in vessels $<100\ \mu\text{m}$ in diameter (Berman *et al.*, 2000). This finding is reinforced by observations that there is a strong negative correlation between the absolute magnitudes of NO- and EDHF-dependent relaxations in rings of superior mesenteric artery from different rabbits (Hutcheson *et al.*, 1999), and that long-term blockade of endothelial NO synthesis potentiates relaxations to EDHF (Kessler *et al.*, 1999). Conversely, EDHF activity is downregulated in sepsis as a direct consequence of the overproduction of NO (Kessler *et al.*, 1999). The nature of the inhibitory action of NO against the EDHF pathway is unknown. It also remains to be determined whether EDHF can function as a “back-up” mechanism that compensates for loss of NO activity, a possibility suggested by impaired NO- and prostanoid-relaxations but preservation of EDHF-type responses in arteries from human subjects subjected to radiation therapy (Sugihara *et al.*, 1999).

Integrated Control of Organ Perfusion

Autoregulation

In many organs, flow is regulated so tightly that it remains virtually constant when the supply pressure varies over the range of ~ 50 to ~ 150 mm Hg. This phenomenon is known as autoregulation and depends on negative feedback interactions between myogenic and metabolic control mechanisms. Increases in supply pressure will initially increase flow, but this will rapidly be restored toward baseline following myogenic constriction caused by the increase in pressure itself, and by secondary constriction due to washout of vasodilator metabolites (Fig. 4). In general, loss of NO activity enhances autoregulation in beds where the ability to control flow is relatively weak. For example, in the isolated rabbit ear—a cutaneous circulation that normally does not autoregulate—the capacity for autoregulation becomes demonstrable following inhibition of eNOS or scavenging of NO with hemoglobin (Griffith and Edwards, 1990a). eNOS in-

Figure 4 Schematic illustrating the complex network of interactions linking changes in microvascular pressure, flow, and metabolite release with NO production. NO may directly modulate parenchymal metabolism in addition to exerting effects which are secondary to changes in flow.

hibition similarly extends the weak autoregulatory range of coronary vessels in isolated guinea pig and rabbit hearts (Ueeda *et al.*, 1992; Pohl *et al.*, 1994). In such beds diminished NO activity unmasks or enhances myogenic constriction, thereby attenuating pressure-induced increases in flow. Indeed, metabolic activity in the rabbit ear is so low that the contribution of metabolites can be discounted: myogenic constriction alone appears sufficient to mediate autoregulation (Griffith and Edwards, 1990a). Enhanced myogenic constriction following loss of NO activity may override metabolic factors, as in the isolated rabbit heart autoregulation occurs in the face of increased lactate release and O_2 extraction (Pohl *et al.*, 1994). Although control of local resistance by washout of the dilator metabolite adenosine is thought to contribute to the ability of the mesenteric circulation to autoregulate flow, eNOS inhibition still enhances the normally weak autoregulation found in this bed (Macedo and Lauth, 1996).

NO plays a less prominent role in the coronary, cerebral, and renal circulations *in vivo*, where there is normally a high intrinsic autoregulatory gain. The dominant effects of eNOS inhibition are then an increase in vascular resistance and an associated reduction in baseline flow such that autoregulation is “reset” with the flow plateau of the pressure–flow relationship depressed by up to 30% (Fig. 5). Although there may be no change in the pressure at which autoregulation first becomes evident or in its physiological efficacy (Wang *et al.*, 1992; Beierwaltes *et al.*, 1992; Baumann *et al.*, 1992; Thompson *et al.*, 1996), there may be a 10–20 mm Hg increase in the pressure that defines the lower autoregulatory break point, for example, in canine kidney and myocardium (Smith and Canty, 1993; Majid and Navar, 1992) and in rat brain (Jones *et al.*, 1999). Some reports also suggest that the upper end of the autoregulated range may be extended to higher pressures (Wang *et al.*, 1992; Talman and Dragon, 1995). This rightward shift in the position of the autoregulatory range along the pressure axis may simply reflect attenuated myogenic dilation at low perfusion pressures and

Figure 5 The effects of eNOS inhibition on autoregulation depend on the balance between myogenic and metabolic mechanisms. (A) In beds where autoregulatory gain is weak, autoregulation is enhanced following loss of NO activity. (B) When there is intrinsically strong autoregulation the plateau in the pressure–flow curve may simply be depressed and shifted to the right. (C) In such beds endothelium-dependent agonists may suppress the ability to autoregulate.

attenuated passive distension at high pressures as a result of the exaggerated constrictor tone that follows loss of NO activity. In beds with high autoregulatory gain such as the kidney, increased endothelium-dependent vasodilation by agonists such as ACh abolishes autoregulation, so that pressure–flow relationships exhibit purely passive characteristics (Gross *et al.*, 1976).

A general picture emerges in which apparent differences in the effects of eNOS inhibition may be explained by differences in the contributions of myogenic and metabolic control relative to the ambient level of NO production (Fig. 5). Interactions between these mechanisms could also underlie regional variations in autoregulation within the same organ. In the rat, for example, eNOS inhibition abolishes autoregulation in cerebral and cerebellar cortices, but not in all deep brain structures (Wang *et al.*, 1992; Tanaka *et al.*, 1993). NO synthesis by neurons and other cell types could contribute to autoregulation in the cerebral circulation in addition to endothelial production (Jones *et al.*, 1999).

Hyperemias

Reactive hyperemia is the term used to denote the dilation that follows transient vascular occlusion. It is particularly pronounced in organs with high metabolic demands. Experimentally, it is usually characterized by three parameters: the peak flow achieved after the release of the occlusion, the duration of the increase in flow, and the flow excess, that is, the product of basal flow and occlusion time subtracted from the total hyperemic flow. Flow-dependent dilation of proximal conduit arteries becomes evident in canine epicardial coronary arteries and the human forearm on restoration of flow, and it may be observed proximal to the occlusion (Hintze and Vatner, 1984; Hayashi *et al.*, 1988; Celermajer *et al.*, 1994). There is an emerging consensus that eNOS inhibition or endothelial impairment reduces the duration of the hyperemic response, although the peak flow and flow excess may not always be affected (Yamabe *et al.*, 1992; Altman *et al.*, 1994; O’Leary *et al.*, 1994; Engelke *et al.*,

1996; Puybasset *et al.*, 1996; Dakak *et al.*, 1998). This is perhaps to be expected, as reactive flow-dependent dilation is maximal only after 1 to 2 min, whereas peak hyperemic flow generally occurs within 15 s (Hintze and Vatner, 1984). An endothelium-independent myogenic dilation that is evoked by the mechanical unloading that occurs during occlusion may also contribute to the peak flow (Koller and Kaley, 1990b).

The overall duration of the hyperemic response increases greatly as occlusion times are extended from periods of seconds to minutes as metabolites accumulate in direct proportion to the length of the occlusion. Flow repayment after coronary occlusion in the dog involves both NO and adenosine, with each mediator separately accounting for up to 30% of the resulting reactive hyperemia (Yamabe *et al.*, 1992). In the isolated guinea pig heart the decrease in flow caused by inhibition of eNOS may actually enhance adenosine formation, which partially compensates for loss of NO activity (Kostic and Schrader, 1992). In some species endothelial prostanoids also contribute to reactive hyperemia in skeletal muscle (Koller and Kaley 1990b), and in the human forearm total excess flow is much lower after combined eNOS and cyclooxygenase inhibition than after eNOS inhibition alone (Engelke *et al.*, 1996). Like adenosine, prostanoids may act in a compensatory fashion. In conscious dogs they normally do not contribute to reactive hyperemia, but prolonged inhibition of eNOS leads to upregulation of prostanoid-dependent dilator mechanisms, so that cyclooxygenase inhibitors then significantly reduce the flow excess after coronary occlusion (Puybasset *et al.*, 1996).

In general, organ blood flow increases in direct proportion to tissue activity, a response that is known as functional or active hyperemia and is dominated by the dilator effects of metabolites on distal arterioles. In some beds NO activity can enhance this hyperemic flow by up to 50%, for example, during cardiac pacing in canine and human myocardium (Jones *et al.*, 1995; Quyyumi *et al.*, 1995), during motor nerve or direct field stimulation in skeletal muscle (Hussain *et al.*, 1992; Hester *et al.*, 1993), and during exercise in rat

hind limb (Hirai *et al.*, 1994). Indeed, in humans, NO is almost entirely responsible for the epicardial coronary dilation observed during pacing (Quyyumi *et al.*, 1995). Intravital microscopy has demonstrated that there may be substantial longitudinal gradients within the same vascular bed in the relative contribution of NO and of metabolic factors. In hamster cremaster muscle, eNOS inhibitors constrict larger arterioles and prevent their dilation during functional hyperemia, whereas the responses of the smallest arterioles are relatively unaffected (Hester *et al.*, 1993). In contrast, in canine myocardium small feed arteries constrict following administration of eNOS inhibitors, whereas distal arterioles may dilate secondary to autoregulatory mechanisms, leading to a reduction in metabolic reserve during pacing (Jones *et al.*, 1995). Perfusion studies with microspheres have shown that the attenuation of functional hyperemia by eNOS inhibitors is most pronounced in muscles with high oxidative capacity during exercise, suggesting that flow-dependent coordination of upstream and downstream responses through NO-dependent mechanisms is particularly important in beds with high perfusion requirements (Hirai *et al.*, 1994). In other beds, enhanced metabolic dilatation of small arterioles compensates for impaired flow-dependent upstream dilation: many studies have failed to demonstrate a role for NO in overall functional hyperemia during exercise, for example, in the human forearm (Endo *et al.*, 1994; Wilson and Kapoor, 1993) and in canine skeletal muscle (O'Leary *et al.*, 1994; Shen *et al.*, 1994) and myocardium (Altman *et al.*, 1994).

Direct Metabolic Effects of NO

NO released from the microvascular endothelium may depress mitochondrial respiration in adjacent parenchymal cells, thus explaining the respective increases and decreases in skeletal and cardiac muscle O₂ consumption that follow administration of eNOS inhibitors or endothelium-dependent agonists (Shen *et al.*, 1995; Xie *et al.*, 1996). This action of NO may involve direct inhibition of cytochrome *c* oxidase, the terminal enzyme of the mitochondrial respiratory chain, which functions as an NO-controlled O₂ sensor regulating the rate of O₂ consumption according to the ambient O₂ concentration (Clementi *et al.*, 1999). In endothelial cells the control of O₂ uptake by NO requires influx of extracellular Ca²⁺, but it is unknown if the Ca²⁺-dependent NOS enzyme involved is eNOS or a mitochondrial isoform located in the inner mitochondrial membrane (Giulivi, 1998; Clementi *et al.*, 1999). The effects of NO on mitochondrial respiration have not been investigated in the context of autoregulation and the hyperemias, although flow-induced increases in NO production might be expected to decrease the formation of dilator metabolites by depressing metabolism, thereby enhancing autoregulation through negative feedback and attenuating hyperemic responses (Fig. 4). The relative lack of effect of eNOS inhibition on hyperemic responses reported in some vascular beds could also reflect a compensatory in-

crease in metabolite formation following an increase in mitochondrial respiration.

Long-Term Regulation and Vascular Disease

eNOS Expression

Expression of the constitutive endothelial NO synthase (eNOS) increases within hours of exposure of endothelial cells to fluid shear stress, thus explaining the enhancement of NO-dependent responses to flow and agonists by exercise training in dogs and rats (Sessa *et al.*, 1994; Uematsu *et al.*, 1995). Upregulation may extend to all beds in which exercise affects flow, as increases in eNOS expression are found in epicardial arteries and coronary/skeletal muscle arterioles, but not in mesenteric arterioles which do not experience increased flow during exercise (Sessa *et al.*, 1994; Sun *et al.*, 1998). Analogously, in high output states induced by creation of an aorto-caval fistula, NO activity is enhanced only proximal to the fistula (Arnal *et al.*, 1993). Cyclic strain at levels comparable to those generated by the pulsatility of blood flow *in vivo* also upregulates eNOS in the absence of flow, so that fluid shear stress may not be the only mechanical force regulating eNOS expression (Awolesi *et al.*, 1995). Long-term changes in ambient flow also modulate the transduction pathways that couple shear forces to the activation of eNOS, as exercise enhances agonist-induced responses by increasing either the number or affinity of the endothelial receptors (Cheng *et al.*, 1999), and G-protein expression and GTPase activity are enhanced in cultured endothelial cells exposed to high levels of shear stress (Redmond *et al.*, 1998).

The mechanisms involved in the upregulation of eNOS by shear stress have some features in common with the acute NO response to flow. Flow-enhanced expression of eNOS mRNA involves a PTX-sensitive G-protein-coupled pathway (Malek *et al.*, 1999), is attenuated by K⁺ channel inhibition (Uematsu *et al.*, 1995), and is Ca²⁺ dependent with the requirement for Ca²⁺ being specific for influx triggered by store depletion (Xiao *et al.*, 1997; Malek *et al.*, 1999). In other respects, however, differences are apparent. eNOS contains a shear stress responsive element (SSRE) that is present in other endothelial genes such as platelet-derived growth factor β chain, in which it is thought to regulate expression by mechanical forces (Marsden *et al.*, 1993). Upregulation of eNOS, however, does not appear to depend on PLC, calmodulin, and tyrosine kinase-dependent mechanisms that affect shear-induced NO production and transcription of such SSRE-containing genes (Uematsu *et al.*, 1995; Xiao *et al.*, 1997; Malek *et al.*, 1999). There is evidence that protein kinase C (PKC) may enhance transcription of eNOS under specific experimental conditions (Li *et al.*, 1998), but this mechanism does not appear to operate under increased shear stress (Ranjan *et al.*, 1995; Uematsu *et al.*, 1995). Nor is the integrity of the endothelial

microtubular network essential for the upregulation of eNOS in response to flow, at least in cultured cells (Malek *et al.*, 1999).

Remodeling

The alterations in vascular wall structure and composition induced by long-term changes in blood flow that lead to normalization of shear stress are multifactorial in etiology, as the endothelium can regulate cell proliferation and extracellular matrix production through both NO-dependent and -independent mechanisms (Garg and Hassid, 1989; De Mey *et al.*, 1991; Tronc *et al.*, 1996). Creation of an arteriovenous fistula in the rabbit carotid circulation leads to increases in carotid artery diameter and remodeling of the media that normalizes wall shear stress, and these adaptive changes are partially attenuated by eNOS inhibition (Tronc *et al.*, 1996). In marked contrast to wild-type mice, remodeling of the carotid artery is prevented in knockout mice with targeted disruption of eNOS (Rudic *et al.*, 1998). eNOS mutants instead display a paradoxical hyperplastic increase in arterial wall thickness, suggesting that NO activity prevents pathological changes in vessel wall morphology (Rudic *et al.*, 1998). Analogously, long-term pharmacological inhibition of eNOS leads to medial thickening and perivascular fibrosis in the rat microvasculature even when the associated hypertension is offset by long-term hypotensive therapy (Numaguchi *et al.*, 1995).

Shear Stress, Superoxide Anions, and Atherosclerosis

Local hemodynamic factors predispose to the development of atheroma on the inner wall of curved arterial segments where time-averaged shear stress is low, and at arterial bifurcations where flow separation and reattachment may lead to oscillatory fluctuations in shear stress (Caro *et al.*, 1971). Observations that high levels of flow prevent or reverse smooth muscle proliferation and neointimal thickening (Kohler *et al.*, 1991; Mattsson *et al.*, 1997), that endothelial dysfunction occurs first at bifurcations (McLenachan *et al.*, 1990), and that NO modulates mass transport processes in the arterial wall (Forster and Weinberg, 1997) suggest that local variations in NO activity could contribute to the focal nature of atherosclerosis. Flow also stimulates production of the O_2^- anion by the endothelium (Laurindo *et al.*, 1994), and there is growing evidence that its reaction with NO is of major importance in the genesis of vascular dysfunction. Superoxide thus attenuates NO activity relative to NO production, and their reaction product ONOO⁻ is a potent oxidant whose toxic effects may contribute to vascular pathology in hypercholesterolemia, hypertension, and diabetes (for review, see Kojda and Harrison, 1999). Short-term elevations in transmural pressure, for example, stimulate O_2^- production in isolated rat arterioles, thereby acutely impairing flow-dependent and agonist-induced dilations (Huang *et al.*, 1998a); on the other hand, sustained hypertension can increase both O_2^- production and eNOS expression, and en-

dothelial dysfunction may then be associated with ONOO⁻-mediated protein nitration (Bouloumie *et al.*, 1997). Importantly, endothelial dysfunction can be reversed by cell-permeant forms of superoxide dismutase (SOD) and antioxidants in a variety of disease states (Kojda and Harrison, 1999).

Different temporal patterns of shear stress may cause specific effects on NO production and endothelial redox state. Steady and periodic laminar shear forces increase the expression of both eNOS and SOD, which can be considered as an antioxidant defense enzyme that adapts to changes in oxidative stress, whereas turbulent flow characterized by high-frequency fluctuations in amplitude and direction is without effect (Noris *et al.*, 1995; Topper *et al.*, 1996). In cells exposed to oscillatory shear forces with zero mean stress, there is a sustained increase in the expression of NADH oxidase, the major source of endothelial O_2^- production, whereas SOD levels remain unchanged (De Keulenaer *et al.*, 1998). In contrast, laminar shear stress induces transient increases in NADH oxidase activity, but increases in SOD expression are sustained. Intracellular levels of O_2^- are consequently lower in endothelial cells exposed to steady laminar shear stress than to purely oscillatory shear forces, a finding which may further help to explain the development of atheroma at specific sites (De Keulenaer *et al.*, 1998). Additional links between hemodynamic forces and endothelial production of NO and O_2^- are suggested by the demonstration that reactive oxygen species generated in response to shear stress regulate protein tyrosine phosphorylation (Yeh *et al.*, 1999) and may also modulate the association of eNOS and caveolin within caveolae (Peterson *et al.*, 1999).

It remains to be determined whether gender-related differences in the incidence of cardiovascular disease involve differences in NO and O_2^- production. NO-mediated flow-dependent dilation is greater in arterioles from female than male rats—a difference that is lost following oophorectomy but restored by estrogen replacement (Huang *et al.*, 1998b). Similar sex-related differences in endothelial function are found clinically (Pinto *et al.*, 1997). Although multiple mechanisms may underlie the vascular effects of estrogens, estrogens have been reported to decrease endothelial O_2^- and ONOO⁻ production, without change in eNOS expression (Barbacanne *et al.*, 1999).

Conclusions

It is now well established that endothelial NO synthesis plays a pivotal role in the control of blood flow, thereby helping to optimize the distribution of microcirculatory flow and to maintain the hydraulic efficiency of the circulation. Hemodynamic forces activate a highly complex array of signaling pathways within the endothelial cell, and the mechanisms through which these regulate NO production and eNOS expression in response to pulsatile blood flow are incompletely understood. Much is also yet to be learned about the interaction of NO with other endothelium-derived mediators, including the superoxide anion, prostanoids, and

EDHF, whose formation may be influenced by mechanical forces. NO participates in long-term remodeling of the vasculature following chronic changes in flow and is now thought to exert an important “anti-inflammatory” action against the development of atherogenesis. However, the extent to which impaired endothelial function contributes directly to the development of disease or is a secondary phenomenon remains to be fully delineated. Although significant advances have been made, further insights are likely to lead to a more precise understanding of acute and chronic vascular responses to local hemodynamic factors, better clinical diagnostic characterization of vascular states, and ultimately, it is hoped, more effective prevention and treatment of vascular disease.

Nitric Oxide Synthase Gene Transfer

Melina R. Kibbe,* Paul C. Lee,* Timothy R. Billiar, and Edith Tzeng

University of Pittsburgh, Department of Surgery, Pittsburgh, Pennsylvania

OWING TO ITS DIVERSE BIOLOGICAL EFFECTS, NITRIC OXIDE (NO) WAS ONE OF THE MOST STUDIED MOLECULES IN THE 1980S AND 1990S. NO HAS COMPLEX FUNCTIONS AND IS A POTENTIAL MEDIATOR IN MANY DISEASE PROCESSES. IT HAS BEEN LINKED TO THE DEVELOPMENT OF VASOMOTOR DYSFUNCTION, INTIMAL HYPERPLASIA, IMPOTENCE, WOUND HEALING, AND TUMORS. WITH THE ADVENT OF RECOMBINANT DNA AND GENE TRANSFER TECHNOLOGIES, DELIVERY OF THE NITRIC OXIDE SYNTHASE (NOS) GENE MAKES LOCAL OVEREXPRESSION OF NO FEASIBLE. THIS IS POTENTIALLY THERAPEUTIC IN A VARIETY OF DISEASES WHERE ADDITIONAL NO MAY BE BENEFICIAL. IN THIS REVIEW, WE DISCUSS THE MERITS AND DRAWBACKS OF DIFFERENT GENE TRANSFER VECTORS INCLUDING RETROVIRUS, ADENOVIRUS, AND ADENO-ASSOCIATED VIRUS AS WELL AS OTHER NONVIRAL GENE TRANSFER METHODS SUCH AS THE USE OF CATIONIC LIPOSOMES AND THE HEMAGGLUTININATING VIRUS OF JAPAN. WE THEN PROVIDE A DETAILED REVIEW OF THE ROLE OF NO IN THE PATHOPHYSIOLOGY OF THE AFOREMENTIONED DISEASES AND THE BENEFITS OF NOS GENE TRANSFER.

Introduction

Historically, nitric oxide (NO) was regarded with little interest beyond its function in ozone destruction and as a by-product of microbial nitrogen metabolism. More interest in NO developed in the late 1970s and early 1980s, when mammalian NO production was recognized and linked to potential roles in inflammation, tumor surveillance, neurotransmission and memory formation, and vascular physiology. In a landmark paper in 1980, Furchgott and Zawadzki reported that acetylcholine, a potent vasodilator, required an intact endothelial cell layer to promote vascular smooth muscle relaxation. They hypothesized that endothelial cells released a labile and diffusible factor in response to acetylcholine that mediated vasorelaxation through cGMP produc-

tion. This endothelium-derived relaxing factor (EDRF) was subsequently identified as NO or an intermediate derivative thereof (Ignarro *et al.*, 1987; Palmer *et al.*, 1987). Since the discovery of NO, its diverse properties and functions have driven the development of NO-based therapies targeting the regulation of vasomotor tone, prevention of arterial injury and transplantation vasculopathy, apoptosis, wound healing, and tumor chemotherapy.

Since the 1980s and 1990s, the development of genetic engineering and gene transfer as modes of investigation and treatment of a variety of disease processes has also been occurring. There has always been a human curiosity to better understand the basic building blocks of living organisms. With the discovery of DNA as the information-bearing molecule and the elucidation of the genetic code, the recombinant DNA era was born. Technologies were developed to purify, sequence, cleave, and paste DNA that allowed the identification of genes and their coding sequences. Armed

with these tools, it was inevitable that genetic engineering would become a reality and gene therapy a goal for the present and the future.

As the studies into the properties of NO progressed, it became clear that NO may have many therapeutic roles that range from preventing vascular pathophysiology to promoting wound healing to tumoricidal actions. Methods of delivering NO to target tissues and organs include systemic administration and local gene therapies. The cloning of the three different NO synthase (NOS) isoforms permitted the development of NOS gene therapies (Table I). Shortcomings of systemic NO delivery include the risk of severe hypotension and potential toxicity to sensitive tissues. NOS gene therapies permit delivery of NO locally to defined target areas, thereby limiting the risk of potential adverse effects of NO and making this mode of NO delivery attractive. The duration of NO production can also be tailored to what is needed for a particular disease process.

Nitric Oxide Synthases

NO biosynthesis begins with a family of enzymes that catalyzes the conversion of L-arginine in a reaction with mo-

lecular oxygen to yield NO and the by-product L-citrulline. There are three distinct NOS isoforms that can carry out this synthetic pathway. Endothelial NOS (eNOS), neuronal NOS (nNOS), and inducible NOS (iNOS) have all been cloned from a variety of species as well as from human tissues. Characterization of these genes revealed that the three isoforms are unique products of three different genes. cDNAs for each of these isoforms have been cloned, sequenced, and demonstrated to encode functional enzymes. The availability of the cDNAs permits the use of NOS gene transfer to investigate the effect of NO on a variety of tissues and organs *in vivo*. The unique characteristics of each NOS isoform, including the enzymatic specific activity, cofactor requirement, and posttranslational regulation, can influence the selection process of which NOS would function in any particular gene therapy protocol. In order to perform NOS gene transfer, the design and selection of the most appropriate gene transfer vectors must be carefully considered.

Gene Transfer Vectors

The study of gene therapy and the ultimate use of gene transfer for the treatment of genetic or acquired diseases rely on efficient and safe vectors with which to deliver a gene of interest. The urgency to develop human gene therapy provides the greatest incentive for rapid innovations in this area. A number of vectors are currently available, but each has advantages as well as limitations that must be acknowledged because of the impact these limitations have on the outcome of experiments and therapies (Table II). For this purpose, several of the most commonly used vectors will be reviewed.

Retrovirus

Retroviruses are RNA viruses that integrate into the normal life cycles of the eukaryotic host cell and harness the host cellular machinery for viral propagation (Tzeng *et al.*, 1996a). The retrovirus has a very simple genome consisting of long terminal repeats (LTRs) and *gag*, *pol*, and *env* regions measuring 8 to 10 kb in length (Miller, 1992). The

Table II Vectors for Vascular Gene Therapy

Vector	Target cell type	Target receptor	Transfer efficiency	Duration of expression	Safety issues
Viral					
Retrovirus	Replicating	Multiple	Low	Months–Years	Insertional mutagenesis
Adenovirus	Replicating and nonreplicating	Coxsackievirus–adenovirus receptor (CAR) and α_v -integrin receptors	High	Weeks	Inflammatory response
Adeno-associated virus (AAV)	Replicating and nonreplicating	Heparan sulfate proteoglycan receptor	High	Months–Years	Insertional mutagenesis, Rep protein toxicity
Other

Hemagglutinating virus of Japan (HVJ)	All	Sialoglycoprotein receptor	Low	Days	None

gag and *pol* regions encode core proteins, a protease, reverse transcriptase, and an integrase. The *env* region encodes the envelope proteins (Varmus, 1988). A single promoter, the LTR, regulates the transcription of viral RNA molecules that can be spliced to yield two different transcripts. Only the full-length transcript carries the packaging signal (Ψ) located upstream of the *gag* region. This packaging signal is essential to the encapsidation of only the appropriate viral RNAs into mature virions (Linial and Miller, 1990).

Retroviruses contain two single-stranded RNA molecules and viral proteins in an icosahedral viral core that is encapsulated by a host cell membrane lipid bilayer and viral glycoproteins (Miller, 1992). Retroviral infection is a receptor-mediated process. Following cell recognition and attachment, viral internalization occurs with release of the viral transcripts, reverse transcriptase, integrase, and protease into the cell. Reverse transcription generates a double-stranded DNA provirus intermediate from the two RNA molecules. The provirus enters the nucleus where viral integration proceeds in a semirandom fashion. The LTRs located at both 5' and 3' ends of the provirus are essential for the integration process. The integrated provirus is then transcribed and translated by the host cell machinery. Progeny viral particles are formed by the packaging of RNA transcripts possessing the Ψ signal, followed by viral release through a budding process of the cell membrane that does not result in cell lysis.

In order to safely use the retrovirus for gene transfer, the virus must be rendered replication incompetent while remaining infectious. The simplicity of the retroviral genome permits the deletion of large segments of the coding sequence without interfering with the packaging and assembly of infectious virions. The only components of the retroviral genome that are essential for successful genomic integration and virion formation are the LTRs and Ψ (Miller, 1992). The *gag*, *pol*, and *env* genes are dispensable as long as an alternate source of the viral proteins and enzymes are provided during viral assembly. The deleted viral genes can be easily replaced by foreign genes measuring up to 8 kb in size. The LTR may serve as the promoter for this foreign coding sequence, or an exogenous promoter may be concurrently inserted. The recombinant retroviral plasmid is then introduced using nonviral transfection methods into packaging cell lines that have been engineered to constitutively synthesize viral proteins necessary for assembly, packaging, and encapsulation of the viral RNA.

The primary advantage of retrovirus-mediated gene transfer is that the transferred genetic material becomes integrated into the host genome in a semipermanent fashion, permitting prolonged gene expression and becoming an inheritable trait. Nabel *et al.* (1990) reported expression of retrovirally transferred marker gene products for up to 5 months after viral exposure in arteries. The theoretical potential for permanent gene transfer using retroviral vectors make them well suited for gene therapies for diseases stemming from genetic disorders such as cystic fibrosis and adenosine deaminase deficiency. Another advantage of retroviral vectors is the simplicity of the retroviral genome. The deletion of essen-

tially all of the coding sequence of the viral genome results in the elimination of viral protein production. Viral antigens can be recognized by the host immune system as foreign and can generate a substantial inflammatory response that would result in the elimination of cells expressing the viral products. Retroviral vectors are associated with little if any inflammatory response and contributes to the longevity of transgene expression.

Even though retroviral vectors were initially looked on as an ideal vehicle for gene delivery, there are some limitations of retroviral gene transfer. The retroviral life cycle requires genomic integration prior to expression of viral gene products, and this integration process requires active cellular proliferation (Miller *et al.*, 1990). Cells that undergo slow turnover or that are quiescent are therefore very poor targets for retroviral gene transfer; this limits the utility of retroviruses to only cells undergoing rapid replication. Additionally, retroviral infection requires specific cell surface receptors that are not abundant on most cell types. This paucity of receptors results in low gene transfer efficiency, especially *in vivo*. For example, retroviral infection in the arterial wall results in transfer efficiency of only 0.1–1.0% (Flugelman *et al.*, 1992; Nabel *et al.*, 1990). Finally, a theoretic concern is that retroviral integration into the host genome may result in the activation of an oncogene, leading to malignant transformation, or may disrupt a vital gene. Such events are semirandom, with some sites preferred over others, but no known events have occurred with retroviral gene transfer that has been associated with oncogenesis or an acquired genetic disorder.

Adenovirus

Human adenoviruses were discovered in 1953 after an exhaustive search for the cause of the common cold. Currently, there are more than 100 different adenoviral serotypes known, of which there are 47 distinct human serotypes (Ad1–Ad47) that are subclassified into six groups (A through F) according to tissue specificity, hemagglutination, oncogenic properties, DNA homology, and virulence (Hierholzer *et al.*, 1988). The two best-characterized and most widely used adenovirus serotypes for gene transfer studies are Ad2 and Ad5, which belong to subgroup C and are primarily respiratory pathogens (Straus, 1984).

The adenovirus is a DNA virus characterized by a complex, nonenveloped, icosahedral outer protein capsid (Stratford-Perricaudet and Perricaudet, 1994; Straus, 1984). The genome consists of a double-stranded linear DNA molecule measuring 36 kb in length with inverted terminal repeats (ITRs) at either end. The genome is packaged within an icosahedral capsid (Hitt *et al.*, 1997) composed of virally encoded capsomers, including 240 hexons and 12 penton bases (Perricaudet and Stratford-Perricaudet, 1995). From each penton base protrudes the fiber coat proteins. Adenoviral infection is a receptor–ligand interaction and, therefore, is limited to cells that express the receptor. Adenovirus fiber coat protein attaches with high affinity to the coxsackievirus–

adenovirus receptor (CAR) (Roelvink *et al.*, 1998; Tomko *et al.*, 1997). After viral attachment, internalization occurs through binding of the adenoviral penton base via an RGD motif to an α_v integrin receptor which, in turn, binds the extracellular matrix protein vitronectin (Wickham *et al.*, 1997). Receptor-mediated endocytosis ensues with release of the contents of the endosome into the cytoplasm of the cell (Seth *et al.*, 1984). The DNA then migrates to the nucleus where it remains as an episome.

In sharp contrast to that of retrovirus, the adenoviral genome is extremely complex with overlapping coding sequences. The adenoviral genome has four early genes that are expressed within 6–8 hours after infection. These are the early region 1 (E1A and E1B), E2 (E2A and E2B), E3, and E4. These genes encode proteins that initiate host cell DNA replication, shut off host protein synthesis, promote viral DNA replication, and protect the adenovirus-infected cell from recognition by host immune surveillance (Babiss *et al.*, 1985). Following viral DNA replication, the late viral genes become activated. Once the late genes are activated, host protein synthesis has essentially been halted, and the focus of the cells is centered on viral replication. The late genes encode structural viral proteins that are required for assembly of the viral core and outer capsid. The portions of the adenoviral genome that encode for the penton base, hexon, and fiber coat protein are the L2, L3, and L5 transcripts, respectively (Hitt *et al.*, 1997). By 30–40 hours postinfection, viral production is nearly complete and these daughter adenoviral particles are released through host cell lysis (Hitt *et al.*, 1997).

The complexity of the adenoviral genome has hindered the development of adenoviral gene transfer vectors because of the difficulty in creating deletional mutants that continue to possess the ability to infect and express a foreign transgene. However, such vectors have been successfully constructed. Adenoviral serotypes 2 and 5 are the most widely used adenoviral vectors because they are the best characterized and their complete DNA sequences are available. They are also nononcogenic in rodents, which is an important safety issue. The majority of the early vectors are E1 region deleted, thereby rendering these vectors replication incompetent. These E1-deleted adenoviral vectors, along with E3-deleted vectors, are termed first-generation recombinant Ad vectors. In place of the E1 gene, a foreign gene with an exogenous promoter up to 3.2 kb in size can be inserted into the adenoviral backbone (Hitt *et al.*, 1997). With additional deletions in the E2, E3, or E4 regions, genes up to 7.5 kb in size can be inserted. The maximal amount of DNA that can be encapsulated in the adenovirus is 38 kb (Berkner, 1992).

Adenovirus possesses several attractive characteristics for gene therapy. First, because adenovirus does not integrate into host genomic DNA, these viruses can target both replicating and quiescent cells alike. This characteristic is attractive for gene therapies directed at slow or nonreplicating cells, such as cardiac myocytes, hepatocytes, vascular smooth muscle cells (VSMC), and endothelial cells. In addition, genes transferred with this vector are not inherited,

and transgene expression is limited to weeks. Second, adenoviral infection is efficient and is essentially complete within several minutes depending on the relative abundance of the CAR receptor. Third, the adenovirus has a particular affinity for human tissues, making it an ideal vector for human genetic therapies. Finally, the adenovirus can be produced in significantly higher titers than other vectors, often reaching 10^{13} plaque-forming units (pfu)/ml.

The adenoviral vector also has its shortcomings. Due to the nonintegrated nature of the adenoviral DNA, expression of the foreign gene is only transient, on the order of weeks. This characteristic may be considered both a potential benefit and a limitation. Transient gene expression may be ideal for disease processes that are acute, such as wound healing or intimal hyperplasia after arterial injury. However, when gene therapy is being directed at chronic and inherited diseases, transient gene delivery is unlikely to impact on disease outcome. Another important shortcoming of the adenoviral vector is the inflammatory response that it evokes. Current first-generation vectors still possess a number of viral genes that are transcribed, translated, and expressed. These viral proteins are recognized as foreign antigens by the host immune system and will evoke an immune response directed at eradicating the cells expressing the foreign proteins. Thus, the host immune response limits the duration of expression of the foreign gene. The immune response of the host will also diminish the success of subsequent attempts to deliver the same vector. The development of second-generation adenoviruses that express fewer viral products will hopefully reduce the inflammatory response and prolong transgene expression.

Adeno-Associated Virus

The adeno-associated virus (AAV) is another vector that has emerged onto the gene therapy scene. It is a member of the parvovirus family that has five different serotypes. AAV serotype 2 (AAV-2) is the most extensively characterized, and its genome has been completely sequenced (Srivastava *et al.*, 1983). AAV-2 virions contain a single-stranded linear DNA molecule that is approximately 4.7 kb long. Both plus and minus strands are packaged with equal frequency and are similarly infectious (Berns, 1990). The virion is encapsulated in a nonenveloped, icosahedral particle (Hoggan *et al.*, 1972). The genome of the AAV consists of two ITRs, a *rep* gene, and a *cap* gene. The *rep* gene encodes four proteins involved in DNA replication, and the *cap* gene encodes three proteins involved in the virion structure (Kotin, 1994). The ITRs are each 145 bases long; the first 125 bases of these repeats fold back on themselves in a T-shaped double strand which serves as the viral origin of DNA replication. Additionally, the ITRs are the only known *cis*-acting elements required for AAV packaging (Trempe, 1996).

Wild-type AAV has two distinct life cycles: latent and lytic. Latent infections occur when AAV infects a cell in the absence of a helper virus. AAV binds to cell surface heparan

sulfate proteoglycans (Summerford and Samulski, 1998). Viral DNA is released into the cytosol, migrates to the nucleus, and becomes integrated into the host genome. Viral integration does not occur in a completely random fashion; approximately 70% of integration events target chromosome 19 (Jolly, 1994). This targeting is believed to be related to the *rep* gene, because *rep* negative vectors do not integrate preferentially into chromosome 19 (Jolly, 1994). Once integrated, AAV exists as an integrated provirus without adversely affecting cell morphology or physiology. Cheung *et al.* (1980) demonstrated persistence of the AAV genome in tissue culture even after 100 passages. The lytic phase of the AAV life cycle is initiated by a helper virus or a cellular stress. When a cell possessing a latent AAV provirus is infected with a helper virus, such as the adenovirus or herpes simplex virus, the AAV genome is excised and enters into viral replication (Cheung *et al.*, 1980; Hoggan *et al.*, 1972). The helper virus provides the necessary gene products in altering host DNA synthesis to favor viral replication (Berns and Giraud, 1996). For example, the adenoviral early genes, namely, E1A, E1B, E2A, and E4, are involved in AAV viral replication.

The general strategy for generating a recombinant AAV vector (rAAV) is relatively straightforward owing to the simplicity of the AAV genome. The *rep* and *cap* genes can be deleted, and a foreign gene, along with an exogenous promoter, measuring up to 4.1–4.9 kb in size, can be inserted (Dong *et al.*, 1996). The ITRs are the only portion of the AAV genome that is required for its life cycle. A plasmid bearing the recombinant AAV and a plasmid bearing the *rep* and *cap* genes are cotransfected into a cell line expressing the necessary adenoviral genes. In the presence of adenoviral proteins, *rep* proteins rescue and amplify the replication of the recombinant AAV genome. The *cap* proteins package the single-stranded rAAV genome into an infectious AAV virion (Trempe, 1996). To isolate AAV virions, these cells are collected 48–72 hours after infection, heated to 56°C to inactivate the adenovirus (if an infectious adenovirus was used), and purified using a CsCl₂ equilibrium gradient. Viral titers produced using this technique have been shown to be as high as 10¹¹ to 10¹² total particles (Salveti *et al.*, 1998). A problem with recombinant AAV vector production has been contamination of viral preparations with infectious helper virus. This has been greatly alleviated by using engineered packaging cells in the absence of infectious adenovirus (Grimm *et al.*, 1998; Salvetti *et al.*, 1998). Additionally, the use of a novel packaging cell line, generated from stably transfecting a *rep/cap*-containing plasmid into HeLa cells, has resulted in a 100-fold amplification and rescue of the AAV genome and in a high yield of recombinant AAV (Gao *et al.*, 1998; Salvetti *et al.*, 1998).

AAV has an unusually broad host range with diverse cell specificity. Lynch *et al.* (1997) infected different cell lines, including vascular cells, and showed a significant variation in the transfer efficiency between the different cells. Human smooth muscle cells (SMCs) infected with 100 DNase-resistant particles (DRP) per cell had a transfer efficiency of

5.2%, whereas rat SMCs had a transfer efficiency of only 0.032%. Human umbilical vein endothelial cells infected with 10 times as much virus revealed a transfer efficiency of 4.5%. Additionally, they demonstrated that rAAV had higher transfer efficiency *in vivo* in injured rat carotid arteries when viral infection was performed several days after creating the injury, indicating that rAAV preferentially infected actively proliferating cells in their model. Others have shown greater transduction efficiencies in vascular cells by infecting with even higher amounts of virus per cell. Maeda *et al.* (1997) were able to infect rat VSMC with a transfer efficiency of 50%. Another group examined the efficiency of gene transfer with the AAV in uninjured rat carotid artery (Arnold *et al.*, 1997) and found that 90% of intimal and medial cells contained the transgene 24 hours after infection, and that this expression could be detected at similar levels 1 month later. Although they did not specifically assay for inflammatory cells, microscopic evaluation did not show evidence of gross inflammation. It should be cautioned, however, that the titers used in this study were low, on the order of 10⁵ IU/ml. Titers used with adenoviral-based gene delivery to the rat carotid artery have ranged from 10⁶ to 10¹⁰ pfu/ml, which is significantly higher and more likely to provoke an immune response.

In summary, the AAV has many advantageous features that make this an ideal vector for gene transfer. Perhaps its most significant contribution will be toward gene therapy for chronic conditions, given that the AAV provirus is integrated into the host genome and has a relatively long duration of expression. This may prove to be the vector of choice when targeting genetic disorders or chronic disease processes such as transplant vasculopathy. Additionally, AAV produces virtually no viral antigenic proteins that can elicit a significant host immune response. Thus, the duration of transgene expression is even longer compared to some other viruses. AAV has a universal appeal secondary to its ability in successfully infecting a broad range of host cell types and species. The virus also appears to be quite safe for use with humans, with no evidence of pathogenicity in humans. Furthermore, the nonrandom integration event can reduce the theoretic mutagenic risk of random integration as seen with retroviruses. It is unknown, however, if this nonrandom insertion pattern will occur with recombinant adeno-associated viruses, since the *rep* gene, which is deleted with most rAAV, may be involved in this process.

One limitation with the use of AAV is that it can only accommodate the insertion of a small transgene (<4.9 kb), thus limiting the genes that can be carried by this vector. Another concern with its use for human gene therapy is that approximately 80% of the human population carry preformed antibodies secondary to prior exposure to the virus (Verma and Somia, 1997). These antibodies may make AAV gene transfer difficult by binding and clearing the vector prior to cellular infection. Currently, there are several ongoing clinical trials with rAAV bearing the cystic fibrosis transmembrane conductance regulator (CFTR) gene for treatment of patients with cystic fibrosis (Flotte *et al.*, 1996; Wagner *et*

al., 1995). Therefore, evaluation of these data may provide significant insight into this potential problem.

Cationic Liposomes

Prior to the advent of viral vectors, most gene transfer studies were performed using chemical methods of DNA delivery. Even today, however, safety concerns about administering infectious virus to humans have driven the continued development of nonviral modes of gene delivery. Cationic liposome complexes are positively charged synthetic lipid vesicles that encapsulate negatively charged DNA, RNA, and antisense molecules. These positively charged complexes fuse with the negatively charged cell membrane and release DNA into the cytoplasm. Typically, naked DNAs in cellular cytoplasm are rapidly degraded by DNases such that only a small percentage of the DNA actually reaches the nucleus. Methods of masking the DNA from cellular nucleases are being developed and should improve the gene transfer efficiency of these nonviral methods. Once in the nucleus, the DNA will remain unintegrated in an extrachromosomal fashion, resulting in a short duration of transgene expression. Various cationic liposome preparations are commercially available, and the efficiency of these preparations will vary with the preparation, the DNA/liposome concentration ratio, the cell type targeted, and the proliferation status of the cell (Feldman and Steg, 1997).

There are many advantageous features of using cationic liposomal-mediated gene transfer. The safety profile of cationic liposomes is superior to many other vectors because of the absence of viral products or viral progeny, the absence of an inflammatory response, and the low risk of insertional mutagenesis. Cationic complexes have been administered systemically via both intravenous and intra-arterial routes and locally, with minimal biochemical, hemodynamic, or cardiac toxicity (Nabel *et al.*, 1992, 1994; Stewart *et al.*, 1992). Construction of the lipid-DNA complex is very simple, and there is no limitation on the quantity of DNA that can be solubilized into the liposomes. These complexes can transfect both proliferating and nonproliferating cells. Disadvantages of cationic liposomes mainly involve the very poor gene transfer efficiency that is achieved, especially *in vivo*.

HVJ-Liposome Complexes

To increase the efficiency of liposomal gene transfer, a mediator of cell attachment and membrane fusion called hemagglutinating virus of Japan (HVJ) has been added to the DNA-containing liposome complexes. Synthesis of this modified fusion liposome is relatively straightforward. The DNA-liposome complex is fused with ultraviolet (UV)-inactivated HVJ virions, and the HVJ-liposomes are purified by sucrose-gradient ultracentrifugation. Subsequent fusion of the HVJ-liposome complex with the plasma membrane introduces the DNA directly into the cytoplasm. In several studies, use of HVJ-liposomes led to much

greater levels of gene transfer than achieved with simple liposomes alone. Using these HVJ-liposomes to transfer genes into vascular smooth muscle *in vivo*, gene expression has been shown to be 10-fold higher than with lipofectin, and the length of liposome incubation with the tissue reduced from 24 hours to 30 min (Morishita *et al.*, 1993). There was no evidence of cellular toxicity, whereas lipofectin caused a significant decrease in cell viability.

Vasomotor Regulation

NO is a potent vasodilator and has been implicated in the regulation of blood pressure and flow in both animal models and human subjects (Dominiczak and Bohr, 1995; Huang *et al.*, 1995; Rees *et al.*, 1989; Vallance *et al.*, 1989). NO interacts with sGC, and the resultant increase in cGMP in the VSMCs leads to relaxation of the muscular layer and dilation of the vessel (Ignarro *et al.*, 1987; Palmer *et al.*, 1987). Endothelial NOS was found to play an even more integral role in determining resting blood pressure when mice genetically lacking the eNOS gene were found to be spontaneously hypertensive (Huang *et al.*, 1995). Additionally, patients with diabetes, hypertension, and atherosclerosis have been shown to have diminished levels of eNOS in their vasculature (Cohen, 1995; Moncada and Higgs, 1993). Therefore, the impact of reduced levels of vascular NO production on hypertension and other vascular pathophysiology has led to the development of gene therapy strategies to restore NO synthetic function to the blood vessel wall (Table III).

Carotid Artery

To determine if eNOS overexpression in the carotid artery could alter vasomotor function, Oobushi *et al.* (1997) collected rabbit carotid arteries and infected them with an adenoviral vector containing the eNOS (AdeNOS) gene using 3×10^9 pfu per arterial ring segment (3 mm in length). Twenty-four hours following infection, transgene expression was confirmed by immunohistochemistry and was localized to both endothelial and adventitial cells. Following precontraction with phenylephrine, vessels infected with AdeNOS demonstrated greater relaxation to acetylcholine than control vessels. A similar response was observed following treatment with the calcium ionophore A23187. To determine if this observed alteration in vascular tone was mediated predominantly by the genetically engineered endothelial cells or adventitial fibroblasts, the experiments were repeated following endothelial denudation. Augmented relaxation was still observed following treatment with A23187. Therefore, overexpression of the eNOS gene in adventitial cells was sufficient to affect vasomotor function.

Since the above study was an *ex vivo* organ culture model, there was a need to determine if vasomotor function could be affected following *in vivo* gene transfer. Therefore, Kullo *et al.* infected rabbit carotid arteries intralumenally with AdeNOS or a control adenovirus for 20 min (Kullo *et al.*,

1997a). Four days following infection they determined that AdeNOS overexpression resulted in increased cGMP release as well as reduced contractions to phenylephrine, in an NO-dependent fashion. Additionally, acetylcholine-mediated vasorelaxation was enhanced in the AdeNOS-transduced vessels. The same investigators then showed that *in vivo* adventitial delivery of eNOS to the rabbit carotid artery could affect vasomotor function (Kullo *et al.*, 1997b). These experiments demonstrate that, by providing excess NO to the vasculature, vascular tone can be altered.

Atherosclerotic Carotid Artery

Delivering eNOS to normal vessels has been quite successful at modulating vasomotor function. Unfortunately, most dysfunctional blood vessels are diseased with atherosclerosis, and it is in this setting that endothelial-dependent relaxation is impaired (Forstermann *et al.*, 1988; Guerra *et al.*, 1989; Zeiher *et al.*, 1993). Although the mechanism of this impairment is poorly understood, possibilities include (1) impaired NO production through either reduced substrate or cofactor availability, or an effect of endogenous inhibitors; (2) enhanced NO scavenging, possibly through the increased production of reactive oxygen species; and/or (3) deleterious effects on downstream mediators of NO activity (Channon *et al.*, 1998). Guerra *et al.* measured NO release in normal and atherosclerotic vessels and found that athero-

sclerotic vessels released less NO than normal vessels. Intravenous administration of L-arginine was found to normalize endothelium-dependent relaxation in hypercholesterolemic rabbit thoracic aorta (Cooke *et al.*, 1991) and hind limb vessels (Girerd *et al.*, 1990). Similarly, administration of L-arginine via intracoronary infusion to hypercholesterolemic patients restored acetylcholine-induced increases in cardiac blood flow (Drexler *et al.*, 1991). However, endothelial cells at sites of atherosclerotic plaques are sources of superoxide anion (Ohara *et al.*, 1993), and this superoxide may interact with NO to generate peroxynitrite, which can result in local toxicity. This potential interaction makes it difficult to predict the outcome of eNOS overexpression in atherosclerotic vessels.

Ooboshi *et al.* (1998) extended their prior observation with eNOS gene transfer to normal carotid arteries to those of the carotid arteries of Watanabe heritable hyperlipidemic (WHHL) rabbits that display mild to moderate atherosclerotic lesions. Using an *ex vivo* organ culture model, the carotid arteries from WHHL rabbits and from New Zealand White (NZW) rabbits were incubated with either Ad β gal or AdeNOS (3×10^9 pfu per artery) for 2 hours. Histochemistry for β -galactosidase and eNOS expression revealed similar patterns of staining among the vessels, with staining of the endothelial and adventitial cells but not the smooth muscle cells. However, expression of eNOS by Western blot analysis was greater in the WHHL than in the NZW carotid

arteries. The effect of eNOS transgene overexpression was analyzed by recording isometric tension in the vessel rings following infection. After precontraction with phenylephrine, acetylcholine produced less relaxation in the atherosclerotic (WHHL) compared to the control (NZW) vessels. However, both atherosclerotic (WHHL) and normal vessels (NZW) following eNOS gene transfer displayed greater relaxation to acetylcholine than control infected vessels. The enhanced relaxation was inhibited with *N*^ω-nitro-L-arginine. This was the first report utilizing adenovirus-mediated eNOS gene transfer to restore NO-mediated responses to acetylcholine in atherosclerotic rabbit carotid arteries. It will be important to examine the long-term consequences of such gene transfer to the arterial wall. Additionally, there may be other added benefits to this form of gene delivery, as some have speculated that long-term overexpression of eNOS in atherosclerotic vessels may lead to regression of existing plaques as a result of the known antiplatelet, antileukocyte, and antiproliferative effects of NO.

Coronary Artery

In 1997, Cable *et al.* investigated whether porcine coronary arteries could be transduced with an adenoviral vector encoding the eNOS gene (Cable *et al.*, 1997a). Using 5×10^9 pfu/ml of AdeNOS or the control adenoviral vector carrying the β -galactosidase gene (AdLacZ) the investigators infected porcine coronary arteries *ex vivo*. Localization studies revealed that endothelial and adventitial cells stained positive for β -galactosidase in AdLacZ-infected vessels, or eNOS in AdeNOS-infected vessels, but that medial smooth muscle cells were not infected. The investigators then performed nitrite measurements and isometric tension recordings. AdeNOS-infected segments produced significantly higher levels of nitrite and displayed greater relaxation to A23187, both of which effects were reversed with NG-monomethyl-L-arginine (L-NMMA). Since this was an *ex vivo* model, it will be important to determine the response of eNOS gene delivery to coronary arteries *in vivo*, perhaps by utilizing a percutaneous endovascular technique, as this will afford us knowledge more applicable to clinical scenarios.

Cerebral Arteries

Chen *et al.* were the first to demonstrate the feasibility of eNOS gene transfer to cerebral arteries using *ex vivo* gene transfer to rings of canine basilar artery (Chen *et al.*, 1997a). They delivered recombinant eNOS in an adenoviral vector using three different titers (10^9 , 10^{10} , and 10^{11} pfu/ml). They found that arterial segments infected with AdeNOS demonstrated concentration-dependent reduction in the contractile responses to UTP and enhanced endothelium-dependent relaxation to the calcium ionophore A23187. They also demonstrated the feasibility of *in vivo* eNOS gene transfer to the cerebrovascular system via the cerebrospinal fluid (CSF) (Chen *et al.*, 1997b). Given that intraluminal gene transfer to the cerebral circulation is limited by risks of cerebral ische-

mia, the importance of demonstrating efficacy of adventitial vascular gene therapy to the cerebral circulation becomes evident. After injecting AdeNOS into the canine CSF via an intracisternal injection using 1×10^9 pfu/ml, they demonstrated increased expression of the eNOS protein in the adventitial fibroblasts of the vascular wall of all major cerebral arteries 24 hours following infection. Next, they demonstrated that AdeNOS-transduced arteries produced significantly higher levels of cGMP compared to AdLacZ-transduced arteries, and that AdeNOS-transduced arteries displayed increased bradykinin-induced relaxations. Both of these findings were reversed with L-NMMA, an inhibitor of eNOS, and the cGMP release was reversed in the absence of calcium, suggesting that these effects were not due to the upregulation of iNOS. Hence, these investigators showed that perivascular eNOS gene transfer is possible to the cerebrovascular circulation and does not require cessation of cerebral blood flow.

In 1998, Tsutsui *et al.* evaluated the efficacy of *ex vivo* gene transfer of eNOS to canine basilar, coronary, and femoral arteries, with and without endothelium, to determine if genetically modified adventitial fibroblasts could restore NO production and regulate vascular tone. Twenty-four hours following *ex vivo* gene transfer, staining for eNOS was predominately localized to adventitial fibroblasts, however, there was some staining of endothelial cells. Basilar artery staining was greater than that in both coronary and femoral artery. With the endothelium intact, bradykinin-induced relaxations were augmented in basilar arteries infected with AdeNOS compared to controls. However, coronary and femoral arteries infected with AdeNOS did not display augmented relaxation. Following removal of the endothelium in the basilar artery, AdeNOS infection still resulted in augmented relaxation to bradykinin. This study reveals two important findings. First, the efficiency and biological response from *ex vivo* adenoviral gene transfer was markedly greater in cerebral arteries than in peripheral arteries. Second, adventitial fibroblasts genetically modified with the eNOS gene were capable of modulating vasomotor tone in the cerebral circulation. This provides important insights concerning the role adventitial fibroblasts may play in maintaining or regulating vascular tone following gene transfer.

The etiology of vasospasm following subarachnoid hemorrhage (SAH) is poorly understood. However, impairment of the L-arginine-NO pathway as a result of increased oxyhemoglobin production has been implicated (Katusic *et al.*, 1993). Additionally, several investigators have shown that supplemental NO in the form of intravenous nitroglycerine (Frazee *et al.*, 1981), intracarotid NO infusion (Afshar *et al.*, 1995), or intracisternal injection of L-arginine or superoxide dismutase (Kajita *et al.*, 1994) can reverse cerebral vasospasm following SAH. Given that the cerebral vasospasm occurs 4 to 12 days after an incident of SAH, attempts to overexpress eNOS to the cerebral vasculature using an adenoviral vector would be ideal. This hypothesis was investigated by Onoue *et al.* (1998), who transferred eNOS using an adenoviral vector to canine basilar arteries *ex vivo* obtained from control dogs and dogs subjected to SAH. They

found that gene expression was twofold higher in arteries from animals suffering from SAH than in normal arteries and that the transgene localized primarily to the adventitia. Relaxation to bradykinin was augmented in arteries from both normal and SAH animals following AdeNOS infection. Additionally, the presence or absence of endothelium did not affect this augmentation, and NOS inhibitors reversed the beneficial effects of eNOS gene transfer, indicating NO-specific effects. Thus, *ex vivo* adventitial eNOS gene transfer was able to restore vasomotor tone to spastic arteries resulting from SAH in dogs. This may prove to be a feasible form of therapy for the alleviation of the devastating complications of cerebral vasospasm associated with subarachnoid hemorrhage.

Systemic Administration

Given the role NO plays in maintaining vasomotor tone, it is logical to hypothesize that systemic delivery of eNOS would attenuate hypertension in spontaneously hypertensive rats (SHR). Lin *et al.* (1997) delivered a single injection of naked eNOS cDNA through the tail vein of SHR and monitored blood pressure, urinary and serum levels of cGMP and nitrite/nitrate, heart rate, body weight, food and water intake, and urine output. The investigators found that systemic delivery of eNOS increased the production and excretion of cGMP and nitrite/nitrate, and was associated with a significant reduction in systolic blood pressure (181.5 ± 1.90 eNOS cDNA versus 195.5 ± 1.2 control) while the other parameters were unaffected. A single reinjection of eNOS cDNA prolonged the beneficial effects for up to 12 weeks. The authors did not evaluate where the transgene was being expressed or determine if certain vascular beds were more susceptible to genetic modulation than others. This may have significant implications for future studies. However, based on these results, the authors concluded that a single intravenous injection of eNOS cDNA may be efficacious in compensating for the dysfunction in the L-arginine–NO pathway in patients with essential hypertension.

Neuronal Nitric Oxide Synthase

Gene transfer of nNOS to the vasculature has also been shown to affect vasomotor tone. Channon *et al.* in 1996 delivered an adenoviral vector encoding the rat nNOS cDNA to human VSMCs and human umbilical vein endothelial cells (HUVECs). Cells infected with AdnNOS expressed increased levels of nNOS protein and exhibited marked NO production in response to A23187, acetylcholine, or bradykinin. Supplementation with the tetrahydrobiopterin precursor sepiapterin further enhanced NOS activity in all cells. To extend these observations to an *in vivo* model, the same investigators delivered a low titer of AdnNOS (6×10^8 pfu for 20 min) to carotid arteries of normal and cholesterol-fed rabbits (Channon *et al.*, 1998). In normal carotid arteries, AdnNOS enhanced endothelium-dependent vascular relaxation to acetylcholine (control $47 \pm 6\%$ versus AdnNOS 86

$\pm 4\%$ reduction in precontracted tension). In the cholesterol-fed rabbits, baseline acetylcholine-induced relaxation was impaired. However, this abnormality was nearly completely corrected following delivery of nNOS to the carotid artery. Thus, both eNOS and nNOS gene transfer successfully restored vasomotor tone in normal and atherosclerotic arteries in different animal models. These studies taken together provide significant evidence that NOS overexpression is beneficial in this setting and that clinical trials should be performed to critically evaluate this form of gene therapy in both normal and atherosclerotic human vessels.

Pulmonary Hypertension

Nitric oxide has been shown to be an important regulatory molecule in the pulmonary vasculature. NO has a number of biological effects that are relevant in the lung: vasodilation, bronchodilation, and inhibition of platelet aggregation, leukocyte adhesion, and pulmonary smooth muscle cell proliferation (Assender *et al.*, 1992; Moncada and Higgs, 1993). NO is an important vasoactive substance that regulates pulmonary blood flow and maintains a low vascular resistance (Roberts *et al.*, 1995). Furthermore, several studies have suggested that NO plays a key role in the pulmonary vascular response to hypoxia. Hypoxia reduces eNOS gene transcription and NO production by transcriptional and posttranscriptional mechanisms (McQuillan *et al.*, 1994). Adnot *et al.* (1991) have shown that chronic hypoxia is associated with loss of NO-mediated relaxation in the pulmonary vasculature. Additionally, patients with pulmonary hypertension were shown to have less eNOS mRNA and protein, and the levels of eNOS mRNA and protein inversely correlated with the severity of pulmonary hypertension (Giaid and Saleh, 1995). Collectively, these results suggest that hypoxia-induced pulmonary hypertension may reflect a deficit in NO activity within the pulmonary vascular endothelium.

A therapeutic increase of NO activity within the lung may be a reasonable strategy in management of pulmonary hypertension. The additive benefits of the anti-inflammatory and bronchodilatory actions associated with NO may also be beneficial in difficult diseases such as obliterative bronchiolitis occurring post-lung transplantation. Gene transfer of NOS into lungs to restore deficient NO activity has the advantage of acting locally and may avoid hypotensive side effects that can occur with systemic NO delivery. Janssens *et al.* (1996) examined the efficacy of adenoviral-mediated eNOS gene transfer in attenuating hypoxic pulmonary vasoconstriction. Aerosol treatments with 3×10^9 pfu of a recombinant adenovirus containing the eNOS cDNA (AdCMV eNOS) to rats resulted in eNOS gene expression in alveoli and pulmonary vasculature as confirmed 4 days postinfection. Concomitant increases in NO activity and cGMP levels were detected. When subjected to hypoxia, the pulmonary artery pressures were significantly attenuated in the AdCMVeNOS-treated rats while systemic blood pressure remained unaffected. These results suggested that eNOS gene

transfer may have therapeutic utility in attenuating hypoxia-induced pulmonary hypertension.

Portal Hypertension

Portal hypertension is a common and significant complication in end-stage liver disease. The elevated portal pressure is a result of increase resistance in the portal venous system and hyperdynamic blood flow. Both fibrosis and active vasoconstriction are important in augmenting intrahepatic resistance in cirrhotic livers (Bhathal and Grossman, 1985). Hepatic stellate cells play an important effector role in maintaining vascular resistance, and endothelium-derived NO has shown to be a critical vasodilator in this setting (Rockey, 1997). Fevery and colleagues (1998) have investigated cirrhotic livers in rat and in humans and found decreased eNOS expression when compared with normal livers. To determine the impact of eNOS levels on portal hypertension, eNOS gene transfer was performed in cirrhotic rat livers using AdeNOS injected into the portal vein. Immunohistochemical analysis confirmed recombinant eNOS expression in sinusoidal-lining cells and this expression was associated with a reduction in mean portal pressures. These results indicate the importance of hepatic NO synthesis in regulating intrahepatic vascular resistance and the potential utility of NOS gene therapy in the palliation of portal hypertension associated with a variety of liver disorders.

Arterial Injury

Restenosis following percutaneous angioplasty remains a significant clinical dilemma. Approximately 30–50% of patients who have undergone angioplasty develop hemodynamically significant stenosis within 3–6 months as a result of intimal hyperplasia. Intraluminal stents have impacted on the patency rates, but restenosis and intimal hyperplasia remain problems. In addition, long-term patency of coronary artery bypass grafts and lower extremity vein grafts remains poor because of intimal thickening at sites of anastomoses. Current therapeutic modalities directed toward preventing this process, including antithrombotics, antioxidants, anti-proliferative agents, and irradiation, have only offered limited benefit. Significant time and effort are being invested into the study of the arterial injury response and elucidating the mechanism of intimal hyperplasia. The rat carotid artery has served as the primary animal model in studying this problem because injury can be easily induced, and the cascade of cellular events has become fairly well understood. Since the 1970s, this simple model has advanced our knowledge of the vascular injury response considerably. The work of investigators such as Clowes, Reidy, Schwartz, Ross, and Nabel, has paved the way for the tremendous amount of research currently devoted to this area of study. Understanding the processes that occur following arterial injury will

provide a better understanding of the logic behind any vascular gene therapy project.

The Vascular Injury Response

Arterial injury, either through balloon angioplasty or as a result of surgical intervention, causes endothelial denudation with possible rupture of the internal elastic lamina (IEL) and damage of the underlying medial SMCs (for reviews, see Clowes, 1997, Clowes *et al.*, 1983a,b, 1986, Reidy, 1992, Reidy *et al.*, 1992, and Ross, 1993). The exposed IEL and SMCs provide a nidus for platelet aggregation (Badimon *et al.*, 1998). Leukocyte adherence follows (Guzman *et al.*, 1995; Skantze *et al.*, 1998), and an array of cytokines and growth factors which have multiple effects are secreted. Basic fibroblast growth factor (bFGF) release is responsible for the first wave of smooth muscle cell proliferation following injury (Lindner *et al.*, 1991; Lindner and Reidy, 1991). Platelet-derived growth factor (PDGF) is mainly responsible for the migration of SMCs from the media to the intima, where the cells continue to proliferate (Fingerle *et al.*, 1989). Transforming growth factor β (TGF- β) potently stimulates interstitial collagen gene expression by human SMCs and results in extracellular matrix deposition (Liau and Chan, 1989). Although these growth factors have different mechanisms of action, there is tremendous redundancy in this regulatory process, as evidenced by studies in which just one growth factor was inhibited with either antibodies or ASOs, with intimal thickening being only partially inhibited.

One of the earliest transcriptional events associated with growth factor stimulation is the expression of nuclear protooncogenes. As early as 30 min postinjury, *c-myc*, *c-fos*, and *c-jun* have been shown to be upregulated in aortic SMCs (Miano *et al.*, 1990). This response persists for only a few hours (Hamon *et al.*, 1995). The products of these oncogenes appear to be transcriptional regulatory proteins that are involved in the G1 phase of the cell cycle and are necessary for progression to the S phase (Pardee, 1989). Therefore, it can be reasoned that gene therapy directed to counter the effects of these protooncogenes could alter the vascular injury response in a favorable manner.

Activation of SMCs by growth factors leads to a change in the SMC phenotype from a contractile to a synthetic phenotype. Medial SMC proliferation begins as early as 24 hours following injury and continues to occur for at least 2 weeks. For SMCs to migrate from the media to the intima, the extracellular matrix and IEL must undergo some degree of degradation. Plasminogen activators, which can lyse clots and activate matrix-degrading enzymes, are upregulated along with matrix metalloproteinases, which degrade collagen and elastin. SMCs then migrate to the intima between 1 and 3 days following injury where they continue to proliferate for several weeks leading to the development of intimal thickening. Concurrently, endothelial regeneration occurs through the stimulation of bFGF within 24 hours after injury and can continue for 6–10 weeks (Lindner *et al.*, 1990). Last, following injury there is a marked upregulation of the

genes that encode for extracellular matrix proteins such as collagen and elastin. Deposition of the extracellular matrix is a significant component of the vascular remodeling that occurs after injury. The end result of this complex process is the development of intimal hyperplasia at the site of arterial injury, and this encroachment of lumen may be alleviated by vascular remodeling with a compensatory increase in vessel diameter.

Vascular gene therapy projects have focused on methods to retard the arterial injury response. Inhibition of any one of the pathways described above may reduce intimal hyperplasia. However, the most successful approaches are ones that target central mechanisms. Gene transfer of NOS is attractive because NO can inhibit many different aspects of the injury response (Fig. 1). In addition to inhibiting platelet aggregation (Radomski *et al.*, 1987a,b) and leukocyte adherence (Kubes *et al.*, 1991) to the injured vasculature, NO inhibits VSMC proliferation and migration (Garg and Hassid, 1989). NO also promotes endothelial cell growth, protects them from lipopolysaccharide (LPS) and cytokine-induced apoptosis (Dimmeler *et al.*, 1997; Tzeng *et al.*, 1997), and has been shown to affect vascular remodeling (Rudic *et al.*, 1998).

Endothelial Nitric Oxide Synthase

One common event that occurs following arterial injury is endothelial disruption. This leads to the loss of the normal source of eNOS and with it the vasoprotective properties of NO. Gene therapy approaches using different NOS isoforms are being utilized to restore or increase NO synthesis at the site of injury in order to attenuate the arterial injury response (Table IV).

In 1995, von der Leyen *et al.* were the first to deliver eNOS cDNA using HVJ-modified liposomes to rat carotid arteries intraluminally following balloon induced injury. This eNOS gene transfer resulted in enhanced relaxation to calcium ionophore A23187 4 days following injury infection as well

as a 70% reduction in the neointima/media ratio by 14 days postinjury. Other investigators have subsequently delivered the eNOS gene to the vasculature. Janssens *et al.* delivered an adenovirus encoding eNOS cDNA to rat carotid arteries following balloon-induced injury (Janssens *et al.*, 1998). AdeNOS-infected arteries experienced a 72% reduction in the intima/media ratio by 2 weeks postinjury, which was associated with a reduction in the 5-bromo-2'-deoxyuridine (BrdU) labeling index ($29 \pm 6\%$ versus $45 \pm 4\%$, $p < 0.05$). Chen *et al.* (1998) used a retrovirus to deliver eNOS to syngeneic rat arterial SMCs. These cells demonstrated increased cGMP release and decreased DNA synthesis and cell proliferation. These SMCs were then seeded onto the luminal surface of balloon-injured rat carotid arteries. Two weeks after SMC seeding, vessels treated with eNOS-engineered SMCs displayed a 37% reduction in neointimal thickness and a threefold increase in vessel diameter. Orally administered NOS inhibitor reversed these effects.

Another vascular bed that is subjected to injury as result of therapeutic maneuvers is the coronary vascular bed. To determine if coronary artery SMCs could support eNOS gene transfer, Kullo *et al.* infected cultured porcine coronary artery SMCs with AdeNOS (Kullo *et al.*, 1997c). AdeNOS-infected cells demonstrated increased nitrite production, increased cGMP release, and inhibited cellular proliferation. Recently, Varenne *et al.* (1998) performed *in vivo* eNOS gene transfer to porcine coronary arteries following angioplasty and demonstrated reduction in neointimal thickness and percent stenosis as compared with control vessels (0.75 ± 0.21 vs. 1.04 ± 0.25 mm, $p = 0.019$; $53 \pm 15\%$ vs. $75 \pm 11\%$, $p = 0.006$, respectively). Therefore, the coronary bed appears to be receptive to eNOS gene transfer with a reduction in intimal hyperplasia and luminal stenosis. Percutaneous delivery of an adenovirus encoding eNOS to coronary arteries following balloon angioplasty is feasible as well as efficacious.

Inducible Nitric Oxide Synthase

Inducible NOS is capable of producing much greater quantities of NO in a sustained, calcium-independent fashion as compared to eNOS. With this increased enzymatic specific activity, the use of iNOS for gene therapy may be advantageous over eNOS. Theoretically, lower levels of iNOS gene transfer would be necessary to achieve the same level of NO production generated by eNOS gene delivery. This is an important consideration when performing gene delivery using viral-based vectors to minimize patient exposure and to reduce the likelihood of an inflammatory reaction. In 1996, Tzeng *et al.* delivered retroviral-mediated human iNOS to isolated porcine arterial segments *ex vivo* (Tzeng *et al.*, 1996b). Vessels infected with iNOS produced more nitrite and cGMP compared to vector-infected vessels. Additionally, myointimal thickening following balloon catheter-induced injury was completely inhibited by 1% iNOS gene transfer. The investigators demonstrated a dependency of the iNOS enzyme on its cofactor tetrahydrobiopterin (BH_4). BH_4 is required for the NOS enzyme to dimerize into an active

Figure 1 Beneficial effects of nitric oxide (NO) in the vasculature. NO exerts its protective effects in the vasculature by several mechanisms: (1) induction of vasorelaxation, (2) inhibition of smooth muscle cell proliferation and migration, (3) inhibition of platelet aggregation, and (4) inhibition of leukocyte adhesion.

Table IV Nitric Oxide Synthase Gene Transfer for Arterial Injury

Author	Gene	Vector	Titer	Model	Effect
von der Leyen <i>et al.</i> (1995)	Bovine eNOS	HVJ ^a	30 µg/ml	Rat carotid artery	70% reduction in neointimal area
Janssens <i>et al.</i> (1998)	Human eNOS	Adenovirus	0.9×10^{10} pfu ^b	Rat carotid artery	72% reduction in I/M ^c area ratio
Chen <i>et al.</i> (1998)	Human eNOS	Retrovirus	5×10^5 cfu ^d /ml	Transfected RASMCs ^e seeded onto the rat carotid artery	37% reduction in neointimal area
Varenne <i>et al.</i> (1998)	Human eNOS	Adenovirus	1.5×10^9 pfu	Pig coronary artery	28% reduction in maximal neointimal thickness
Shears <i>et al.</i> (1998)	Human iNOS	Adenovirus	2×10^6 pfu	Rat carotid artery	98% reduction in I/M area ratio
Shears <i>et al.</i> (1998)	Human iNOS	Adenovirus	5×10^8 pfu	Pig iliac artery	52% reduction in I/M area ratio

quaternary structure (Tzeng *et al.*, 1995). Hence, if the supply of BH₄ is low, iNOS function will not be optimized. By providing excess exogenous BH₄, Tzeng *et al.* demonstrated greater nitrite and cGMP production compared to cells transduced with the iNOS gene alone (Tzeng *et al.*, 1996c). Another method to increase the supply of BH₄ is to overexpress the rate-limiting enzyme involved in the synthesis of BH₄, namely, guanosine triphosphate cyclohydrolase I (GTPCH). Delivery of human GTPCH to rat aortic SMC and 3T3 cells infected with a retroviral iNOS vector resulted in increased NO production in these BH₄-deficient cell types (Tzeng *et al.*, 1996c). Thus, it is possible to maximize the efficiency of the iNOS enzyme through gene transfer of the GTPCH gene or by providing exogenous BH₄. Whether this will be a significant concern with *in vivo* studies remains to be determined.

Shears *et al.* (1998) demonstrated that *in vivo* adenoviral delivery of the human iNOS gene (AdiNOS) to injured rat and pig arteries was efficacious in preventing the development of intimal hyperplasia. First, AdiNOS transferred intraluminally to the rat carotid artery following balloon-induced injury was performed using very low titers of virus (2×10^6 pfu/artery) as compared to other gene therapy studies. Evaluation of the carotid arteries 2 weeks following injury and AdiNOS infection showed a 96.7% inhibition of intimal hyperplasia. This effect was NO dependent. Additionally, the inhibition of intimal hyperplasia persisted in animals sacrificed 6 weeks following injury and infection. The efficacy of iNOS gene transfer was also assessed in a model more relevant to humans, namely, the pig iliac artery injury model. Delivery of AdiNOS, again in low titers (5×10^8 pfu/artery), resulted in a 51.8% reduction in the intima/media area ratio in the vessels. This study demonstrated that infection with very low titers of AdiNOS was able to have profound effects in two different animal models of arterial injury. For clinical trials, one can see why it would be advantageous in many ways to be able to deliver such low titers. Demand versus supply in the production of adenoviral vectors encoding NOS enzymes is one very important issue that would be

mitigated by using such low titers. Additionally, the concern of evoking the host immune response would be lessened using such low titers. Therefore, both eNOS and iNOS gene transfer to the vasculature have proved successful in different animal models of arterial injury. Because the arteries that will be targeted for these therapies will not be normal, these same experiments must be repeated in atherosclerotic vessels to fully evaluate the efficacy of NOS gene therapy in inhibiting intimal hyperplasia.

Vein Graft Intimal Hyperplasia

Late vein graft failure has been a daunting problem since bypass surgery was first developed. Approximately 25% of peripheral artery vein bypass grafts fail within the first 5 years (Taylor *et al.*, 1990), and 32% of coronary artery bypass grafts fail within 10 years (Lawrie *et al.*, 1991). The etiology of this late failure is due to the development of intimal hyperplasia or progression of the underlying atherosclerotic vascular disease (FitzGibbon *et al.*, 1986; Karayannacos *et al.*, 1978). The pathophysiology of vein graft intimal hyperplasia is poorly understood. However, vein grafts have impaired endothelium-dependent relaxation when implanted into the arterial circulation (Cross *et al.*, 1988; Miller *et al.*, 1987). Likewise, supplemental dietary L-arginine resulted in the reduction of atherosclerotic lesions and intimal hyperplasia with preservation of vasomotor function in animal models of vein grafts (Davies *et al.*, 1994, 1995).

Given the impairment of the NO pathway in vein grafts and the finding that NOS gene transfer successfully inhibits neointimal formation following balloon injury in arteries, it was hypothesized that overexpression of eNOS in vein grafts may attenuate the development of intimal hyperplasia and restore vasomotor function. Cable *et al.* exposed segments of human saphenous vein to AdiNOS in an *ex vivo* organ culture system (Cable *et al.*, 1997b). Immunohistochemical staining for eNOS localized enzyme expression in the endo-

thelium and the adventitia of the veins. Nitrite generation following stimulation with a calcium ionophore increased in segments infected with AdeNOS, but not in control segments. On examination of isometric tension recordings 48 hours following infection, vein segments infected with AdeNOS demonstrated augmented relaxation to calcium ionophore when compared to control vein segments. Hence, gene transfer of eNOS to vein segments using this *ex vivo* model was able to regulate vasomotor function.

More important will be the examination of vasomotor function following eNOS gene transfer *in vivo* over a longer period of investigation. Whether overexpression of eNOS in vein segments placed into the arterial circulation will result in persistent biological function has yet to be determined. This is important because, as noted, the endothelial cells and adventitial cells were transduced. A vein segment placed in the arterial circulation typically loses its endothelial cell layer through cell involution and denudation before becoming re-endothelialized (Ramos *et al.*, 1976). Hence, it is possible that only the adventitial cells initially infected with eNOS would remain to produce NO, and whether this is sufficient to effect a biological response needs to be investigated. Matsumoto *et al.* (1998) performed *in vivo* experiments with eNOS gene transfer to vein grafts. These investigators transferred bovine eNOS cDNA encapsulated in HVJ-liposomes to femoral veins of dogs using pressure-mediated distension (100 mm Hg) of the vein grafts for 10 min. These veins were then implanted as a reverse vein graft in an end-to-end fashion to the ipsilateral femoral artery. Under conditions of surgically created poor distal run-off, veins infected with the eNOS gene displayed a 55% reduction in neointimal area compared to sham-treated grafts evaluated 4 weeks following surgery. Using this model, the investigators found gene expression in the medial SMCs and adventitial cells in the vein wall. Thus, this study provides evidence that eNOS overexpression in vein grafts can affect long-term parameters, such as vein graft intimal hyperplasia. Evaluating these vein grafts at 1 year will provide even more important data, as the pathophysiology of the vein graft intimal hyperplasia is quite different from intimal hyperplasia following isolated arterial injury. Vein grafts are exposed to the continuous insult of the arterial circulation. The development of medial hypertrophy to a certain extent is desirable in the arterialization of the vein, and inhibition of this process may have detrimental sequela. Therefore, while this form of gene therapy has proved to be quite successful in these models, much remains to be learned about the long-term effects of NOS gene therapy in vein grafts.

Transplant Arteriosclerosis

Despite the success of modern cardiac transplantation, the development of accelerated coronary arteriosclerosis, also known as transplantation vasculopathy, has become a major obstacle to long-term allograft survival. It is the major cause of allograft dysfunction and late death in patients (Kaye, 1993; Weis and von Scheidt, 1997). Unfortunately, patients

usually remain asymptomatic until the arteriosclerosis is advanced, manifested clinically by the development of ventricular arrhythmias, congestive heart failure, or sudden death. In a multi-institutional study by Costanzo and colleagues, the likelihood of angiographically visible allograft arteriosclerosis at 1, 2, and 4 years was 11, 22, and 45%, respectively (Costanzo *et al.*, 1998). This progressive disease is characterized by diffuse narrowing of the coronary arteries due to intimal hyperplasia as a result of abnormal medial SMC proliferation followed by migration to the intima (Tanaka *et al.*, 1995).

Although the exact pathogenesis of allograft arteriosclerosis has not been determined, several experimental studies indicate that it is an immune-mediated disease. Incompletely suppressed cellular and humoral immune responses directed toward disparate major histocompatibility antigens expressed on the endothelial surfaces of the allograft initiate an immune-mediated endothelial injury (Russell *et al.*, 1994a,b). This injury is then followed by the infiltration of activated macrophages and lymphocytes into the vessel wall and the initiation of the inflammatory cascade. Endothelial damage leads to exposure of the underlying SMCs to various mitogenic growth factors (Davis *et al.*, 1996). These activated SMCs are then converted from a normal, contractile nonproliferating phenotype to a secretory, proliferating phenotype (Suzuki *et al.*, 1995). The final pathologic lesion observed in the neointima of allograft arteriosclerosis consists of concentric intimal accumulation of SMC and late intimal fibrosis.

NO has been implicated as a potential mediator in each of the steps involved in the development of the transplant arteriosclerotic lesion. Russell *et al.* (1995) demonstrated in the Lewis to F344 rat cardiac transplantation model that iNOS transcription is significantly upregulated in cardiac allografts during both the acute and chronic stages of rejection extending from day 7 to day 75 posttransplantation. At all time points, iNOS was detected predominantly in the mononuclear inflammatory cells within the interstitium and perivascular spaces of the allograft. Akyurek *et al.* (1996) reported that iNOS expression was increased in the intima and adventitia of arteriosclerotic vessels in a rat aortic transplant model. Colocalization studies identified SMCs and macrophages as the cells expressing iNOS. Expression of iNOS in the media decreased over time, presumably due to the migration of medial SMCs to the intima. In a separate study by Lafond-Walker and colleagues (1997) examining coronary arteries of transplanted human hearts with accelerated allograft arteriosclerosis, iNOS mRNA and protein were found to be upregulated in macrophages. Despite these animal and human studies showing that iNOS is upregulated in transplant arteriosclerosis, the consequences of this upregulation remained unclear.

Adverse Effects of Nitric Oxide

Inducible NOS has been shown to contribute to the inflammatory process mediating transplant arteriosclerosis. Russell *et al.* (1995) modulated the inflammatory response

in rats with a diet deficient in essential fatty acids and reported significant reduction in the intimal thickening and percentage of diseased vessels in cardiac allografts. There was a correlated decrease in iNOS mRNA levels, suggesting that NO contributes to the inflammatory response mediating transplant arteriosclerosis. Indeed, high levels of NO has been shown to be cytotoxic to neighboring cells or even to the cells that are producing it (Moncada *et al.*, 1991). The targets of such cytotoxic actions have shown to be the iron-centered enzymes involved in mitochondrial respiration, aconitase activity, and DNA synthesis (Dusting and Macdonald, 1995). Another mechanism for NO induced cytotoxicity is through its interaction with superoxide anion (O_2^-). A product of the reaction between these two free radicals is the highly toxic peroxynitrite anion ($ONOO^-$), capable of initiating free radical-mediated lipid peroxidation and sulfhydryl oxidation (Beckman *et al.*, 1990). Peroxynitrite has been shown to induce permanent vascular dysfunction in isolated hearts (Villa *et al.*, 1994). Furthermore, addition of superoxide dismutase prevented peroxynitrite formation as well as vascular endothelial injury (Beckman *et al.*, 1990).

Cytoprotective Effects of Nitric Oxide

Despite the potential adverse effects of NO, there is a large body of literature indicating that NO is protective against intimal hyperplasia following arterial injury and in transplant arteriosclerosis. These protective effects are attributed to the ability of NO to inhibit SMC migration and proliferation (Garg and Hassid, 1989; Sarkar *et al.*, 1996) as well as to inhibit platelet (Mellion *et al.*, 1983) and neutrophil adhesion (Kubes *et al.*, 1991) (Fig. 1). Lou and co-workers demonstrated in a rabbit heterotopic heart transplantation model that dietary supplementation with L-arginine significantly attenuated intimal hyperplasia in allograft coronary arteries, presumably by suppressing SMC proliferative response (Lou *et al.*, 1996).

In transplant arteriosclerosis, immune-mediated injury to the vascular endothelium might induce the expression of adhesion molecules such as selectins and integrins on the endothelial cells. The adhesion molecules interact with ligands on platelets and leukocytes, and these cell-cell interactions can contribute to subsequent thrombus and lesion formation. NO may help maintain the integrity of the vascular endothelium by inhibiting adhesion molecule expression. NO has direct platelet actions by inhibiting ADP-induced human platelet aggregation, which is mediated by a cGMP-dependent mechanism (Mellion *et al.*, 1983). Furthermore, NO produced from platelets during platelet aggregation inhibits the extent of further platelet activation (Broekman *et al.*, 1991). These studies suggest that NO may protect against thrombus formation on the endothelium after transplantation. Conversely, impaired NO activity in damaged endothelium predisposes to formation of thrombi. NO has been shown *in vitro* and *in vivo* to attenuate leukocyte adhesion and chemotaxis, important steps in arteriosclerotic formation. Enhanced leukocyte adhesion to venular endothelium

during infusion of NOS inhibitors has been reported, and this effect was reversed by administering L-arginine or an antibody to the leukocyte adhesion complex CD11b/CD18 (Kubes *et al.*, 1991). In another study, NO inhibited monocyte chemotaxis *in vitro* via a cGMP-dependent pathway (Bath, 1993). These observations, along with others, suggest that NO blocks inflammatory cell adhesion and migration into the intimal space, thereby limiting the deleterious effects of the inflammatory cascade and development of transplant arteriosclerosis.

Inducible Nitric Oxide Synthase Gene Therapy

It is possible that iNOS-mediated effects on the endothelial and vascular SMC function may differ during acute and chronic conditions (Liu *et al.*, 1998). Although acute iNOS-mediated effects may contribute to endothelial cell injury, NO may play a protective role under chronic conditions, possibly by suppressing intimal SMC accumulation. Indeed, cardiac transplantation into recipient iNOS $-/-$ knockout mice resulted in acceleration of allograft arteriosclerosis (Koglin *et al.*, 1998). These findings suggest that during chronic rejection, iNOS activity protects allografts by suppressing intimal thickening.

Previous experiments performed in our laboratory corroborated these findings. Shears and co-workers (1997) showed in a model of ACI to Wistar Furth rat aortic allograft transplantation that iNOS mRNA and protein as well as intimal thickness were significantly increased by 28 days post-transplantation. Inhibiting NO production with an iNOS inhibitor, L-N^G-(1-iminoethyl)-lysine (L-NIL), increased the intimal width by 57%, indicating that NO participates in suppressing allograft arteriosclerosis. The effects of cyclosporine (CsA) on iNOS expression and allograft arteriosclerosis were also investigated. CsA inhibited iNOS expression in aortic allografts and was also associated with a 65% increase in intimal thickening. These results indicate that even low levels of rejection are associated with an increase in iNOS expression and that this iNOS expression may play a role in limiting the development of intimal thickening so often seen with transplant vasculopathy. Using an adenoviral vector carrying the human iNOS cDNA (AdiNOS) to deliver supraphysiological levels of iNOS and NO to the allograft, allograft arteriosclerosis was dramatically inhibited in recipient animals infected with AdiNOS compared to those infected with AdLacZ. The presence or absence of CsA in the animals infected with iNOS did not affect the beneficial results. This experiment supported that iNOS expression in allografts is important in protecting the allograft and that iNOS gene transfer strategies may have great therapeutic potential in preventing the development of allograft arteriosclerosis.

In contemplating iNOS gene therapy for allograft vasculopathy, the proper gene delivery vector is vitally important. Allograft arteriosclerosis is believed to reflect the outcome of chronic rejection. Chronic rejection, even in the face of appropriate pharmacologic immunosuppression, is an ongoing process for the life span of the allograft. Therefore, iNOS

gene therapy for the prevention of arteriosclerosis would be best served by the use of a vector that permits long-term transgene expression such as retrovirus or AAV. If, however, the pathogenesis of allograft vasculopathy is initiated by an early rejection event that is then propagated by the use of iNOS-inhibiting immunosuppression such as CsA, transient iNOS gene delivery may suffice and provide supplemental NO until vascular healing has occurred. These are all important considerations that must be further evaluated.

Lung Transplant Rejection

Jeppsson *et al.* (1998) investigated the efficiency, distribution, and toxicity of transbronchial adenovirus-mediated eNOS gene transfer to transplanted lungs with the future goal of potentially modulating acute or chronic rejection following lung transplantation. Syngeneic orthotopic single-lung transplantation was performed in rats with transbronchial administration of AdeNOS. Endothelial NOS transgene expression was confirmed by polymerase chain reaction (PCR) and reverse transcriptase PCR (RT-PCR). More than 75% of the pneumocytes stained for eNOS in the AdeNOS-treated group, and a significant increase in NOS activity was also detected. There was no significant difference in the amount of inflammation between control and AdeNOS-treated animals. Therefore, the feasibility of transbronchial eNOS gene transfer to transplanted lungs suggests an alternate and perhaps safer and easier route of AdeNOS administration than via a vascular route. Future studies examining the effects such gene transfer actually has on transplant rejection will further our knowledge on the role of eNOS in this pathophysiological process.

Erectile Dysfunction

Erectile dysfunction, a problem afflicting 10–15 million men in the United States, is mainly a function of inadequate relaxation of the penile corpora cavernosal smooth muscle during sexual stimulation (Murray *et al.*, 1995). NO has been shown to be the main mediator of penile erection (Ignarro *et al.*, 1990; Burnett *et al.*, 1992; Rajfer *et al.*, 1992). NO is released from penile nonadrenergic, noncholinergic nerve terminals and activates soluble guanylyl cyclase, leading to cGMP release in the penile smooth muscle. Cyclic GMP mediates a reduction in intracellular Ca^{2+} and results in relaxation of the penile corpora cavernosal smooth muscle. The engorgement and entrapment of blood in the corporal sinusoids result in penile tumescence. Unraveling the role of NO in penile physiology has led to the development of many pharmacologic agents directed at increasing penile NO activity to treat impotence. The widely publicized and utilized drug Viagra (sildenafil) is a potent phosphodiesterase inhibitor that prevents the degradation of cGMP in the corpus

cavernosum, thus prolonging and augmenting the action of endogenously produced NO.

Another therapeutic approach has been directed at augmenting local NO production by stimulating NO synthase. Garban and colleagues (1997) investigated whether high levels of NO production by either cytokine stimulation of iNOS or following iNOS gene therapy can mitigate age-associated erectile dysfunction in the rat. Continuous infusion of iNOS inducers consisting of a mixture of bacterial lipopolysaccharide, rat γ -interferon, tumor necrosis factor α (TNF- α), and interleukin-1 β (IL-1 β) into the penile corpora cavernosa of old rats significantly corrected aging-associated erectile dysfunction. Western blot assays confirmed the upregulation of endogenous iNOS protein within the penile tissue. These investigators subsequently cloned the iNOS cDNA from rat corpora cavernosa and demonstrated that a single intracavernosal injection of an expression plasmid containing the rat penile iNOS cDNA also corrected age-associated erectile dysfunction in rats. Expression of recombinant iNOS was confirmed in cavernosal tissue by PCR. These results demonstrated that NOS gene transfer is a feasible strategy in the management of erectile dysfunction. However, there are concerns about prolonged NOS gene expression with resultant priapism. Mechanisms will have to be devised to control levels of NOS gene expression or NO production in order to prevent such an outcome.

Wound Healing

Attempts to elucidate the factors regulating wound healing have revealed a dependence on arginine metabolism and the NO synthase pathway (Albina *et al.*, 1990). End products of NO synthesis, nitrite and nitrate, were found to be transiently elevated in fluid collected from sponges implanted in subcutaneous wounds (Albina *et al.*, 1990). Systemic administration of arginine, the substrate for NO synthesis, enhanced wound healing (Barbul *et al.*, 1990; Kirk *et al.*, 1993). Topical application of an NO donor has been shown to accelerate closure of excisional wounds in rats (Shabani *et al.*, 1996), whereas NOS inhibitors given systemically (Schaffer *et al.*, 1996) or applied locally to wounds (Bulgrin *et al.*, 1995) have resulted in retardation of wound healing.

Studies have shown that NO plays a role in collagen matrix deposition, a process necessary in healing wounds. In models of impaired wound healing induced by malnutrition or diabetes, reductions in both wound collagen and NO levels were measured (Schaffer *et al.*, 1996, 1997). Moreover, systemic administration of the NOS inhibitor *S*-methylisothiouonium impaired wound collagen accumulation in mice (Schaffer *et al.*, 1996). Thornton and colleagues (1998) investigated the effect of iNOS gene delivery to cutaneous wounds using subcutaneously implanted polyvinyl alcohol sponges instilled with a mammalian expression plasmid (pMP6) containing the murine iNOS cDNA in rats that had received a dorsal midline incision. They observed that cells within the wound had efficient gene transfer with maximal

iNOS expression measured by 48 hours. By 7 days post-implantation, the iNOS expression plasmid-impregnated sponges had significantly greater collagen content than control sponges, implicating the role of NO in enhancing wound collagen deposition.

Previous experiments in our laboratory examined the role of iNOS in wound closure and explored the impact of topical iNOS gene transfer on the rate of wound healing (Yamasaki *et al.*, 1998). In iNOS $-/-$ knockout mice, wound repair was delayed by 31% compared to wild-type mice. A similar delay in wound closure was seen in wild-type mice treated with a continuous infusion of L-NIL. Wound closure rates in iNOS $-/-$ mice could be accelerated to a rate comparable to that in wild-type mice with a single topical application of AdiNOS at the time of wounding. Inducible NOS mRNA expression was confirmed in treated mice by PCR. This study demonstrated a critical role for iNOS in wound repair and the feasibility of topical iNOS gene transfer therapy. Future application of such gene therapy strategy may be possible in the setting of iNOS-deficient states such as in diabetes and during steroid treatment.

Cancer

Nitric oxide has been implicated in both tumor biology and tumor surveillance. It has been shown to be involved in virtually all components of solid tumor growth, such as tumor angiogenesis, infiltrating inflammatory cells, and tumor cells themselves (Vamvakas and Schmidt, 1997). High levels of NO produced from either iNOS expressed in activated macrophages and endothelial cells or exogenous NO donors can have cytotoxic effects on tumor cells. These cytotoxic effects can include inhibition of cell proliferation or the induction of apoptosis (Cifone *et al.*, 1995; Li *et al.*, 1991; Xie *et al.*, 1997a). Supraphysiological levels of NO may impair DNA synthesis, glycolysis, cellular respiration, or the citric acid cycle. NO-induced tumor cytotoxicity may also be mediated through its interaction with superoxide anion (O_2^-) and the generation of the highly toxic peroxynitrite anion ($ONOO^-$). Although peroxynitrite is very reactive, it is stable enough to diffuse to surrounding tumor cells and initiate free radical-mediated lipid peroxidation and sulfhydryl oxidation (Beckman *et al.*, 1990).

A direct correlation between expression of iNOS and regression of metastatic murine sarcoma has been reported (Xie *et al.*, 1995). Furthermore, the induction of iNOS expression by cytokines in the same model induced apoptosis in tumor cells *in vitro* and *in vivo*. Similar NO-mediated apoptosis was observed in metastatic murine K-1735 melanoma. After induction with different cytokines or LPS, primary nonmetastatic tumor cells demonstrate high levels of iNOS expression and NO synthesis, whereas tumor cells isolated from metastatic lesions have a much lower NO expression (Xie *et al.*, 1996). In dramatic contrast to its tumoricidal activities, NO has also been reported to facilitate angiogenesis within tumors and promote tumor growth. Endogenous

NO activity has been shown to have a direct correlation with tumor grade in some human carcinomas (Jenkins *et al.*, 1995). Therefore, NO appears to have a dual action on tumor development. The precise effect NO has on a particular tumor may be related to local concentrations, the susceptibility of different tumors to NO, or the pleomorphic regulatory signals acting in these tumors (Vamvakas and Schmidt, 1997). NOS activity was two orders of magnitude lower during conditions when NO promoted tumor growth (Jenkins *et al.*, 1995). By activating differential signaling mechanisms, NO can initiate both tumorigenesis and tumor toxicity (Fig. 2). Low NO concentration might activate soluble guanylyl cyclases with a resulting increase in the second messenger molecule cGMP (Schmidt *et al.*, 1993). This could in turn stimulate the endothelial cell migration and proliferation (Ziche *et al.*, 1994) that are essential to tumor neovascularization and tumor development. Low concentrations of NO can also have a protective effect by preventing apoptosis (Kim *et al.*, 1997). Furthermore, NO may be tumorigenic itself. Nguyen *et al.* (1992) reported that NO can cause mutations by increasing DNA strand breaks and mediating the deamination of S-methylcytosine to thymine, and others have implicated increased iNOS activity in the genesis of certain human cancers (Bartsch *et al.*, 1992).

Equipped with the understanding of the dual actions of NO on cancer, one can attempt to achieve a therapeutic potential for NO by maximizing the local NO activity within tumors to inhibit tumor cell proliferation and to induce apoptosis. One way to do this is to supply NO with NO donor compounds. Indeed, Pipili-Synetos *et al.* (1995) showed that isosorbide mononitrate and dinitrate inhibited angiogenesis and tumor growth as well as prevented metastasis. Alternatively, endogenous NO production may be stimulated by induction of iNOS by various cytokines, such as TNF- α . Tumor necrosis factor α can activate both NO and O_2^- pro-

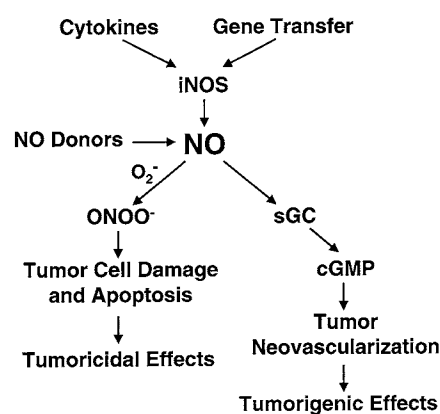

Figure 2 Dual tumoricidal and tumorigenic effects of nitric oxide (NO). NO donors, cytokine, and nitric oxide synthase (NOS) gene transfer therapies can all result in overproduction of NO. Interaction of NO with superoxide anion (O_2^-) yields highly toxic peroxynitrite ($ONOO^-$), ultimately leading to tumor cell killing. However, low levels of NO might activate soluble guanylyl cyclase (sGC), resulting in an increase in cyclic guanosine monophosphate (cGMP) and tumor neovascularization.

duction, providing an environment ideal for the generation of the highly toxic peroxynitrite (McCall and Vallance, 1992). Unfortunately, high-dose cytokine therapy is not a feasible mode of increasing local iNOS expression.

A more practical and direct method of locally increasing NO production is through the transfer of the iNOS cDNA to tumor cells. Transfer of iNOS into tumor cells has been successfully carried out by Xie *et al.* (1995) and by Ambs *et al.* (1998). Ambs *et al.* transfected human carcinoma cells expressing either a functional wild-type p53 or a nonfunctional mutated p53 gene with a retroviral vector carrying the human iNOS cDNA (DFGiNOS) (Tzeng *et al.*, 1995). Transfected cells carrying wild-type p53 and producing NO constitutively exhibited reduced tumor growth in athymic nude mice. Cells carrying mutated p53 and producing NO had accelerated tumor growth. This accelerated tumor growth was associated with increased vascular endothelial growth factor expression and neovascularization. These results suggest that, in some selective tumor cells with mutant p53, NO production might promote their growth. A role for p53 in determining the effect of NO on tumor cells may exist. Treatment of the tumors carrying a mutant p53 with inhibitors of iNOS may have therapeutic potential (Ambs *et al.*, 1998), whereas tumors with a normal p53 gene may be better treated with iNOS gene transfer to augment NO synthesis.

The role of NO and tumor metastasis has been examined. Highly metastatic murine K-1735 melanoma cells, which normally express low levels of iNOS, were transfected with a functional iNOS gene (Xie *et al.*, 1995). Cells overexpressing iNOS were then cultured, harvested, and injected intravenously into mice. The iNOS-transfected cells lost their metastatic potential and underwent apoptosis within 48 to 72 hours after tumor injection. Similarly, human renal carcinoma cells infected with retroviral vectors containing murine macrophage iNOS cDNA were injected into nude mice and produced few if any lung metastases, whereas injection of control cells resulted in large numbers of metastases (Juang *et al.*, 1998). Therefore, this form of gene therapy represents another way to manipulate tumor growth and development.

High levels of endogenous NO cause lysis of bystander cells in addition to autolysis of transfected cells (Xie *et al.*, 1997b). Murine K-1735 C4 parental melanoma cells transfected with an iNOS expression plasmid underwent autolysis that was NO mediated. When these cells were mixed with control cells, the control cells also underwent lysis, demonstrating a bystander effect as a result of the diffusible nature of NO. By engineering a few cells within a tumor to synthesize high levels of NO, tumor lysis may still be induced. These studies of iNOS gene transfer indicate that high local NO production can be achieved in tumor cells and may be used to treat primary tumors and prevent metastatic disease (Juang *et al.*, 1998).

Endothelial NOS gene transfer has also been applied to the treatment of tumors (Liu *et al.*, 1998). Liu *et al.* performed stable transfection of eNOS cDNA in human oral carcinoma cells. Similar to the results achieved with iNOS

gene transfer, eNOS-transfected cells had a lower growth rate compared with control cells. When these eNOS-engineered tumor cells were injected into nude mice, tumor growth was retarded during the first 25 days, but then tumor growth exceeded that of control tumors. The ineffectiveness of eNOS gene transfer to limit tumor growth *in vivo* may be due to the lower levels of NO generated as compared with iNOS gene transfer. Alternatively, a different set of regulatory signals can be turned on by eNOS that may favor tumor growth *in vivo*. Further studies are necessary in elucidating these cellular signaling mechanisms.

NITRIC OXIDE (NO) EXERTS CRITICAL AND DIVERSE FUNCTIONS IN THE CARDIOVASCULAR SYSTEM. AN IMPAIRED NO PRODUCTION AND/OR FUNCTION CONTRIBUTES TO THE PATHOPHYSIOLOGY OF A VARIETY OF CARDIOVASCULAR DISEASES. ALTHOUGH NO THERAPY IS DESIRABLE, THE SHORT HALF-LIFE OF NO AND THE TOLERANCE AND SIDE EFFECTS OF NO DONORS LIMIT THE EFFECTIVENESS OF THEIR CLINICAL APPLICATIONS. SINCE 1996, RECOMBINANT NO SYNTHASE (NOS) GENE TRANSFER HAS BEEN SUCCESSFULLY CARRIED OUT BOTH *EX VIVO* AND *IN VIVO* IN VARIOUS ANIMAL MODELS OF CARDIOVASCULAR DISEASE AND HUMAN BLOOD VESSELS WITH ENCOURAGING RESULTS. THIS CHAPTER PROVIDES AN OVERVIEW OF THE CONCEPT AND PRINCIPLES OF NOS GENE THERAPY FOR A NUMBER OF CARDIOVASCULAR DISEASES INCLUDING ATHEROSCLEROSIS AND THROMBOSIS, RESTENOSIS, CEREBRAL VASOSPASM, TRANSPLANT VASCULOPATHY, HYPERTENSION, DIABETES MELLITUS, CORONARY HEART DISEASE, IMPOTENCY, AND DELAYED WOUND HEALING. IN ADDITION, THE LIMITATIONS OF THE CURRENTLY AVAILABLE VECTORS AND TECHNICAL MEANS OF NOS GENE DELIVERY TO THE CARDIOVASCULAR SYSTEM ARE DISCUSSED.

Introduction

Nitric oxide (NO) exerts critical and diverse functions in the cardiovascular system, as has been discussed in depth in other chapters in this book. Impairment of NO production and/or function plays a key role in a number of cardiovascular disease processes, including atherosclerosis and thrombosis, restenosis, cerebral vasospasm, transplant vasculopathy, hypertension, diabetes mellitus, coronary heart

disease, impotency, and delayed wound healing (Cooke and Dzau, 1997). Although NO therapy under these circumstances is beneficial and highly desirable, the short half-life (several seconds) and high reactivity of NO and the tolerance and other unwanted effects caused by some NO donor agents (e.g., hypotension) often limit the effectiveness of their clinical applications. On the other hand, the excessive production of NO induced by immunological stimuli under certain diseased conditions (e.g., sepsis-induced hypotensive shock)

contributes to the pathology of these diseases and thus to the logic for selectively inhibiting individual isoforms of nitric oxide synthase (NOS) (Higgs *et al.*, 1999).

Gene therapy refers to the transfer of functional genes to the host tissue to correct the malfunction of a specific gene or to replace a missing gene, with resultant alleviation of the symptoms of a particular disease. Cardiovascular gene transfer is not only a powerful technique for studying vascular biology, but also a novel and promising strategy for treating cardiovascular disease. Beginning in the late 1990s, a number of investigators including our group have begun to explore the functional influences of NOS gene transfer to the cardiovascular system, aiming initially at a variety of animal models of cardiovascular disease, with the long-term goal of applying this technology in future human therapy. Since 1996, NOS gene transfer studies have been successfully carried out both *ex vivo* and *in vivo* in different cardiovascular tissues with encouraging results (A. F. Y. Chen *et al.*, 1998a, 1999). This chapter provides an overview of the concept and principles of NOS gene therapy for cardiovascular disease and the currently available technical means of NOS gene delivery to the cardiovascular system.

Principles of Cardiovascular Gene Therapy

Concept of Gene Transfer and Therapy

Somatic gene therapy has a fundamental distinction from germ-line gene manipulation. In the former, gene expression is modified only in somatic cells, whereas in latter, permanent changes are made in the germ-line. In animal species, manipulation of germ-line genes is useful in that it provides models of human genetic disease, helps to elucidate the functions of novel genes, facilitates the large-scale production of recombinant therapeutic proteins, and even creates genetically modified animal tissues transferable to humans (i.e., xenotransplantation). In contrast, alterations in the human gene pool are clearly not the aim of somatic human gene therapy. In pharmacological and therapeutic terms, gene therapy can be considered to be the use of functional genes in treatment of diseases. In this regard, a prodrug gene (e.g., a NOS cDNA) is delivered to a host by an appropriate vector, via a chosen route of administration (e.g., intraluminal, perivascular), resulting in the release of the active drug (e.g., NO) after biotransformation processes of the genetic prodrug

(Table I). Thus, an ideal system for gene delivery should consist of a safe formula (the vector) and a drug (the gene product) with maximal therapeutic effects and minimal side effects.

Vectors for Cardiovascular Gene Transfer

The success of gene therapy depends, to a large extent, on the effectiveness with which the vector system can deliver the functional gene to the host tissue. An ideal vector for cardiovascular gene delivery should have several characteristics. Such would be the capacity to achieve efficient transduction *in vivo* in both dividing and nondividing vascular cells; maintenance of stable transgene expression for a desired duration; inability to induce immune response and/or mutagenesis in the host cells. In general, two categories of vector system exist: viral and nonviral vectors (Verma and Somia, 1997). Nonviral vectors are either in the form of naked DNA or plasmid DNA in conjugates (e.g., liposomes, molecular conjugates). Although nonviral vectors possess a very good safety profile for human gene therapy, various attempts to use them for cardiovascular gene transfer have been unsuccessful, attributable to their inability of achieving efficacious *in vivo* transgene expression.

Viral vectors are produced from wild-type viruses by genetic engineering. The recombinant viruses are rendered replication incompetent by deletion of the particular portions of the viral genome responsible for initiating transcription. However, their ability to infect via interaction of their surface proteins with the receptors on the host cells is maintained. There are a number of viral vectors available for cardiovascular gene transfer. Retroviruses can integrate into the host cell genome and are thus capable of achieving prolonged transgene expression. However, only dividing cells can be transduced—a major drawback for cardiovascular gene transfer. Recombinant adenoviruses are perhaps the most efficient vascular gene transfer vector currently available, owing to their ability to transduce both dividing and nondividing vascular cells with high efficiency, and to grow to the high titers [i.e., up to 10^{12} plaque-forming units (pfu)/ml] required for *in vivo* gene transfer (Schneider and French, 1993; Wilson, 1996). But the use of these vectors for human gene therapy has currently been limited by the inflammatory response they provoke in host cells (see later). More recently, an ultraviolet light-inactivated hemagglutinating virus of

Table I Gene Therapy versus Traditional Drug Therapy

	Drug therapy	Gene therapy
Prodrug	A compound containing the active drug	A functional gene
Drug	The active compound	The gene product (RNA, enzyme, protein, etc.)
Biotransformation	Metabolic or enzymatic conversion of prodrug	Transcriptional and/or translational conversion of transgene
Formulation	Coated tablets or capsules, solutions, etc.	Viral or nonviral vector solutions, powders, etc.
Route of administration	Oral, intramuscular, intravenous, etc.	Intraluminal, perivascular, etc.

Japan (HVJ; Sendai virus), a member of the mouse parainfluenza virus family, has been combined with multi- or unilamellar liposomes for cardiovascular gene transfer with 30 to 50% transduction efficiency rate and limited toxicity (Dzau *et al.*, 1996; Yonemitsu *et al.*, 1998). In addition, adeno-associated virus and lentivirus are currently being developed to address the limitations of other viral vectors (Verma and Somia, 1997) (compared in Table II).

Adenoviral Vectors and Receptors

BIOLOGY OF ADENOVIRUSES

There are 47 human adenovirus serotypes, divided into six groups (A–F), among the more than 100 serotypes identified in animal species since the 1960s, based on their individual type-specific antigens. The human serotypes 2 and 5 in subgroup C are the two best characterized and most frequently used types as gene transfer vectors. Adenoviruses are double-stranded, nonenveloped linear DNA viruses of approximately 36 kilobases in size that contain hexon, fiber protein, and penton base in their icosahedral capsid.

There are four early regions (E1–E4) of adenoviral genome expressed during the initial stages of host infection. The region essential for viral replication is E1 (E1A and E1B). This region encodes for a number of multifunctional regulatory proteins responsible for transactivation of other early genes involved in the replication cycle. The E2 region has two transcription units which encode both a DNA-binding protein (DBP) and a DNA polymerase (Ad pol) involved in viral replication. The E3-encoded proteins such as the 19-kDa glycoprotein play an important role in modulating

the host immune responses, as they are associated with the major histocompatibility complex (MHC) class I molecules. The functions of the E4 region include facilitation of DNA replication and late viral gene expression and protein synthesis as well as inhibition of host protein synthesis. The first generation recombinant adenoviral vectors are rendered replication-incompetent after the deletion of the E1 region from the viral genome. Deletion of other early regions (e.g., E2, E3, and E4) has been used for construction of a second generation of adenoviral vectors. Foreign genes are then inserted as expression cassettes under the control of heterologous eukaryotic or viral promoters. (Wilson, 1996; Hitt *et al.*, 1997).

Several features of adenovirus biology make recombinant adenoviruses the choice for gene transfer studies in the cardiovascular system. Adenoviral vectors can readily be propagated and purified to yield high-titer stocks. A broad spectrum of vascular cells (both dividing and quiescent) and tissues of different species including human can be transduced by adenovirus *ex vivo* and *in vivo* at high efficiency. In addition, since adenoviruses remain episomal after entering the host cell nucleus, random insertional mutagenesis is not a concern.

PROBLEMS WITH FIRST AND SECOND GENERATION ADENOVIRAL VECTORS

Despite the obvious advantages, the currently available adenoviral vectors possess a number of problems which impede their successful use in human gene therapy today. Although the first and second generations of adenoviral vectors are replication incompetent, owing to deletion of the E1 or

Table II Cardiovascular Gene Transfer Vectors

	Advantages	Disadvantages
Viral vectors		
Retrovirus	Stable chromosomal integration High efficiency for <i>ex vivo</i> transduction Long-term transgene expression	Transduces only dividing cells Inefficient <i>in vivo</i> transduction Limited gene size (~7 kb)
Adenovirus	Transduces nondividing cells High efficiency High vector titers (~10 ¹² pfu/ml)	Host immune responses Episomal (transient expression) Limited gene size (~7 kb)
Adeno-associated virus	Transduces nondividing cells Not associated with known human diseases Naturally replication deficient	Often low efficiency Requires helper viruses Limited gene size (~4.7 kb)
Lentivirus (e.g., HIV)	Transduces nondividing cells Stable <i>in vivo</i> transgene expression	Biosafety concerns Cytopathogenic?
Nonviral vectors		
Naked DNA	Easy to prepare No limit to gene size Safe	Episomal (transient expression) Low efficiency Nontropism
Anionic and cationic liposomes	Transduces nondividing cells No limit to gene size Safe	Episomal (transient expression) Low efficiency Nontropism
DNA–protein molecular conjugates (e.g., poly-L-lysine, HVJ-liposomes)	No limit to gene size Safe	Episomal (transient expression) Transduces nondividing cells

E1 and other early regions, residual viral proteins can be expressed in the transduced host cells. As a result, both a cellular (i.e., CD4⁺, CD8⁺ T cells) and a humoral (i.e., hexon-specific neutralizing antibodies produced by B cells) immune response is evoked. The host immunity not only limits the duration of transgene expression but also prevents the repeated administration of the virus. In addition, adult humans have a high prevalence of preexisting immunity to adenovirus serotypes 2 and 5. In contrast, most experimental animal species lack prior exposure to human adenoviruses (Schulick *et al.*, 1997).

NEWER ADENOVIRAL VECTORS FOR CARDIOVASCULAR GENE TRANSFER

In more recent years, a number of advances in the design and improvement of adenoviral vectors have been reported. These modifications aim to block either the expression of the immunogenic viral proteins or the host immune response. Most recently, the third generation adenoviral vectors, deleted of all viral coding sequences, have been constructed. These vectors offer the prospect of decreased host immune responses, decreased cellular toxicity, and increased capacity to accommodate large cDNA inserts. The use of these “gutted” vectors has resulted in persistent transgene expression, with a diminished immune response (Kochanek *et al.*, 1996; Haecker *et al.*, 1996; H.-H. Chen *et al.*, 1997; Schiedner *et al.*, 1998; Burcin *et al.*, 1999). In addition, cell type-specific and inducible promoters for cell targeting and transcriptionally targeted and regulatory vectors are being developed, further contributing to the optimization and refinement of the vectors for human gene therapy (Nabel, 1999). An adenoviral vector under the transcriptional control of a smooth muscle cell-specific promoter SM-22 has been shown to selectively transduce vascular smooth muscle cells *in vivo* (S. Kim *et al.*, 1997). Technological advances in vector development may thus in the not too distant future allow the results of animal gene transfer studies to be applied in clinical gene therapy trials.

RECEPTORS FOR ADENOVIRUSES

The terminal domain of the adenoviral fiber protein known as the “knob” is involved in viral uptake into the host cells, through a process involving viral receptor-mediated endocytosis. The primary receptor responsible for this process has been cloned, a receptor shared by coxsackie B virus (a RNA virus) and adenovirus serotypes 2 and 5 termed CAR (Bergelson *et al.*, 1997; Tomko *et al.*, 1997). The receptor is a 46-kDa transmembrane glycoprotein consisting of 365 amino acids. Sequence analysis reveals that it belongs to the immunoglobulin (Ig) gene superfamily with two extracellular immunoglobulin-like domains. The adenovirus-binding activity of CAR is localized in the amino-terminal IgV-related domain, which is also shared by adenovirus serotype 12 (Freimuth *et al.*, 1999). Moreover, the deduced amino acid sequences are highly homologous between human and mouse CAR (i.e., 91%) (Bergelson *et al.*, 1998). The localization of human serotype 2 adenoviral receptor has been

mapped to chromosome 21 (Mayr and Freimuth, 1997). The functionality of the receptor has been established because transfection of CAR cDNA in cell lines without native CAR leads to CAR expression with marked transgene expression following adenoviral-mediated marked β -galactosidase gene transfer in these cells (Roelvink *et al.*, 1998).

In addition to the fiber knob protein, the penton base of the viral capsid plays an important role in the internalization of the virus after CAR-mediated endocytosis. It possesses a typical Arg-Gly-Asp (RGD) sequence that facilitates the viral entry through its interaction with $\alpha_v\beta_{3/5}$ integrin, this adhesion receptor which serves as the secondary receptor for the virus, is also involved in vitronectin/fibronectin receptor-mediated cell adhesion. Once the virus enters the host cell nucleus, the viral genome is not integrated into that of the host cells but remains episomal. Hence, adenoviruses are not known to be associated with human malignancy (Hitt *et al.*, 1997).

TROPISM OF CAR DISTRIBUTION AND HETEROGENEITY OF TRANSGENE EXPRESSION

The identification of CAR as a functional receptor for adenovirus and its tissue distribution is likely to have great significance in targeted gene delivery to specific cardiovascular tissues. Northern blot analysis reveals that the mRNA for CAR is strongly expressed in human heart, brain, and pancreas, while its expression is weak in the liver, lung, and lymphocytes, and absent in the kidney, placenta, skeletal muscle, and spleen (Bergelson *et al.*, 1997; Tomko *et al.*, 1997). The lack of CAR expression results in resistance to adenoviral infection and inefficient transgene expression in well-differentiated ciliated airway epithelial cells (Zabner *et al.*, 1997; Pickles *et al.*, 1998), this mechanism perhaps accounting for the failure of initial gene therapy in cystic fibrosis. Indeed, the adenovirus fiber protein largely determines viral tropism, through interaction with CAR, because the infectivity of fiberless adenoviruses deleted of the fiber gene (thus without CAR) is diminished (Legrand *et al.*, 1999; von Seggern *et al.*, 1999). In addition, CAR may also be involved in assembly or maturation of certain viral structural proteins, as the processing of these proteins in the fiber mutants is defective. As a result, although the binding to the cellular integrins was functional in the fiberless viruses, the later step in the cell entry process is impaired due to the defect of the structural proteins associated with the lack of fiber in the viral particle. On the other hand, the ectopic expression of CAR in human dermal fibroblasts that express a relative low level of CAR, or lymphocytes that lack native CAR, results in significant transduction following adenovirus-mediated gene transfer (Leon *et al.*, 1998; Hidaka *et al.*, 1999). In the vasculature, the mRNA for CAR can be detected in human cerebral arteries, and heterogeneity existing between cerebral and peripheral arteries for adenoviral mediated recombinant eNOS expression may reflect differential CAR expression in these vessels (A. F. Y. Chen, *et al.*, 1998b; Tsutsui *et al.*, 1998). Hence, the efficacy of transgene expression mediated by adenovirus may be related to the degree of

CAR expression in different vascular tissues and cells. Future studies on the regulation and manipulation of viral receptor expression will not only provide insights regarding adenoviral-mediated gene expression, but may also help to achieve efficient transduction both *ex vivo* and *in vivo* in different tissues and cells for human gene therapy. Alternatively, the adenoviral tropism can be expanded through genetic modification of the fiber knob domain (e.g., incorporation of a RGD sequence into the H1 loop), resulting in the ability of the virus to utilize an alternative receptor during the cell entry process in CAR-deficient cells (Dmitriev *et al.*, 1998; Hidaka *et al.*, 1999).

Rationale for Gene Transfer of Nitric Oxide Synthases

Nitric oxide synthases catalyze the formation of NO from L-arginine. Three isoforms of NOS enzymes have been isolated and purified to date, and the genes encoding the three isoforms have been cloned. Human endothelial NOS (eNOS), neuronal NOS (nNOS), and inducible NOS (iNOS) genes are located on human chromosomes 7, 12, and 17, respectively. Of the three NOS isozymes, eNOS and nNOS are constitutively active in response to increases in intracellular Ca^{2+} and subsequent Ca^{2+} -calmodulin binding. They usually produce NO in physiological amounts (i.e., in nanomolar range) on demand (in seconds). In contrast, the activity of iNOS is usually Ca^{2+} independent, and its expression following immunological challenges requires a longer time for activation (in hours). However, once iNOS is expressed, it is capable of generating large amounts of NO (i.e., in the micromolar range) hence probably contributing to pathological events (Mayer and Hemmens, 1997). All three NOS isoforms are expressed throughout the cardiovascular system (Ignarro, 1996). Targeted disruption or addition of the three NOS genes in transgenic mice has provided useful animal models for probing the functional importance of each NOS isoform (Huang and Fishman, 1996). In eNOS knockout mice, for instance, vascular phenotypic changes result not only in chronic systemic and pulmonary hypertension with impaired endothelium-dependent relaxation, but also smooth muscle and myocyte cell proliferation in response to arterial injury or hypoxia (Huang *et al.*, 1995; Shesely *et al.*, 1996; Faraci *et al.*, 1998; Rudic *et al.*, 1998; Steudel *et al.*, 1998). Furthermore, a deficiency in eNOS might indicate a genetic predisposition to intimal proliferation, possibly enhanced in males. In females, however, the genetic predisposition may be overridden by pregnancy (Moroi *et al.*, 1998). Conversely, hypotension and, interestingly, decreased NO-mediated vasodilations have been observed in transgenic mice overexpressing eNOS (Ohashi *et al.*, 1998). Potential cardiovascular protective functions for NO include augmentation of vasodilation, promotion of endothelial cell growth, inhibition of leukocyte adhesion, platelet adhesion and aggregation, leukocyte-platelet-endothelial cell interactions,

Pulmonary hypertension	Wound healing
Essential hypertension	

endothelial cell apoptosis, smooth muscle cell proliferation, and synthesis of various matrix proteins (Ignarro, 1996; Cooke and Dzau, 1997). These biological properties of NO form the basis of potential NOS gene therapy for a number of cardiovascular disorders in which a dysfunctional L-arginine-NO-cGMP pathway exists (Table III).

NOS Gene Transfer and Cardiovascular Disease

Proliferative Vascular Diseases

Cell proliferation contributes to the pathophysiology of many vascular disorders including atherosclerosis, thrombosis, restenosis, transplant vasculopathy, and wound healing. Several prominent features exist in the proliferative processes, including thrombus formation, inflammatory cell infiltration within the intima and adventitia, endothelial cell apoptosis, intimal hyperplasia, extracellular matrix synthesis, and impaired recoil of the vessel wall (Gibbons, 1998). Gene therapy represents an attractive approach and an active area of research through which functional genes can be delivered to a local site, in order to inhibit the proliferative response to injury (Nabel, 1995). A number of candidate genes have been used for gene transfer to selectively inhibit one or more growth pathways involved in cell proliferation (Nabel, 1998; Braun-Dullaeus *et al.*, 1998). Overexpression of antiplatelet and antithrombotic proteins such as tissue plasminogen activator (t-PA) or hirudin can prevent platelet aggregation and thrombosis at the site of injury, resulting in decreased release of platelet-derived growth factors (PDGFs). The herpes simplex virus thymidine kinase (HSV-tk) gene can be expressed, and cells that express the transgene can phosphorylate the nucleoside analog ganciclovir, resulting in formation of an active toxic metabolite and leading to inhibition of DNA replication and cell death. Alternatively, since the transition from G_1 to S phase in the cell cycle requires cyclin/cyclin-dependent kinase (CDK) complex, natural inhibitors of cyclin-CDK (e.g., p21, p27) or antisense oligonucleotides against cyclin-CDK (e.g., *c-myb*, cdk 2 kinase, proliferating-cell nuclear antigen, or their transcription factor, E2F) have been delivered to disrupt cell replication.

However, it appears unlikely that inhibition of a limited number of growth pathways will completely abate the com-

plex process of vascular proliferation in response to injury. NO is a pleiotropic molecule that influences a number of cellular processes central to vascular proliferative disease, including inhibition of leukocyte adhesion, platelet adhesion and aggregation, smooth muscle cell proliferation, and synthesis of matrix proteins. Consequently, gene transfer of NOS may provide a pleiotropic therapeutic strategy for suppression or modification of the response to injury. Specifically, enhanced NO production from recombinant NOS expression may provide continuous NO supply to inhibit platelet activation, leukocyte infiltration, platelet-leukocyte interaction, migration of smooth muscle cells and adventitial

fibroblasts, endothelial cell apoptosis, and matrix synthesis, while stimulating beneficial responses such as re-endothelialization and increased blood flow. In pursuit of these concepts, *ex vivo* and *in vivo* NOS gene transfer approaches have more recently been carried out in cell cultures, isolated vessels, and normal and diseased animal models (Tables IV–VI).

CULTURED CELLS

Endothelial and smooth muscle cells of the vasculature constitute important targets for site-specific vascular wall therapy, with the intent of modifying the arterial response to

injury. Endothelial dysfunction and attenuated endothelium-dependent relaxations are manifested in vascular diseases such as atherosclerosis, hypertension, and diabetes, thus providing the logic for endothelial cells as targets. On the other hand, smooth muscle cell response to arterial injury is involved in vascular proliferative diseases such as atherosclerosis, hypertension, and intimal hyperplasia and restenosis after coronary angioplasty. Expression of recombinant NOS in endothelial and/or smooth muscle cells may prove useful in site-specific therapy of these diseases.

NO is a potent inhibitor of both smooth muscle cell and cardiac myocyte growth in response to remodeling. Loss of NO effect results in hyperplasia or ventricular hypertrophy in eNOS knockout mice subjected to arterial ligation or hypoxia, respectively (Rudic *et al.*, 1998; Steudel *et al.*, 1998). NO suppresses smooth muscle mitogenesis by inhibiting protein kinase C (PKC) activity (Guh *et al.*, 1998), blocking cell cycle progression at multiple phases (e.g., G_0/G_1 , S) via activation of cyclin-dependent kinase inhibitors such as p21 (Ishida *et al.*, 1997; Sciorati *et al.*, 1997; Sarkar *et al.*, 1997a,b), or through induction of apoptosis (Iwashina *et al.*, 1998). By contrast, compelling evidence indicates that NO

is a strong inhibitor of endothelial cell apoptosis (Dimmeler and Zeiher, 1997; Y.-M. Kim *et al.*, 1999). NO abrogates angiotensin II, endotoxin, and tumor necrosis factor alpha (TNF- α) induced apoptosis in endothelial cells by interfering with the activation of the protease family of caspase cascade and Bcl-2 cleavage (Dimmeler *et al.*, 1997a,b), and NF- κ B DNA binding activity (DeMeester *et al.*, 1998), respectively. The possible cellular mechanisms through which NO exerts its antiapoptotic effect include induction of cytoprotective stress proteins [e.g., heme oxygenase, heat-shock protein 70 (Hsp70)], cGMP-dependent activation of protein kinase G (PKG) and suppression of caspase activation and activity, and inhibition of cytochrome *c* release from mitochondria (Y.-M. Kim *et al.*, 1999).

The effects of recombinant NOS gene expression have been investigated in cultured endothelial and smooth muscle cells from human and animal species. In porcine coronary arterial smooth muscle cells, adenoviral mediated eNOS gene transfer increases eNOS enzymatic activity, and NO₂ and cGMP formation (Kullo *et al.*, 1997a). Serum-induced cell proliferation is inhibited 3 or 6 days after transduction, attributable to decreased DNA synthesis, when measured by

thymidine uptake. In rat pulmonary smooth muscle cells and sheep pulmonary endothelial cells, retroviral vector-mediated iNOS gene transfer increases iNOS mRNA and protein levels with increased NO₂ production (Tzeng *et al.*, 1996). Interestingly, in smooth muscle cells tetrahydrobiopterin (BH₄), an essential cofactor of NOS, augments eNOS-stimulated cGMP production and iNOS-induced NO production. Likewise, the transduction of cultured guinea pig coronary smooth muscle cells with the eNOS gene also results in recombinant eNOS expression in more than 90% of the cells after 48 hours (Fang *et al.*, 1997). Recombinant eNOS expression inhibits platelet-derived growth factor (PDGF)-stimulated tyrosine phosphorylation of two key molecules implicated in the cell adhesion process, paxillin and focal adhesion kinase (FAK), suggesting the FAK–paxillin pathway as a target for NO-mediated inhibition of cell migration and proliferation.

Similar to eNOS gene transfer, adenoviral mediated nNOS gene transfer resulted in recombinant nNOS expression in cultured human smooth muscle cells and umbilical vein endothelial cells (Channon *et al.*, 1996). Both cell types showed increased NO production in response to Ca²⁺ ionophore A23187, acetylcholine (ACh), or bradykinin stimulation 3 days after gene transfer. Supplement of the BH₄ precursor sepiapterin significantly augmented NO production in nNOS-transduced cells.

In sheep pulmonary endothelial cells, iNOS transduction by either adenovirus or retrovirus vectors, increased NO production in a viral titer-dependent fashion (Tzeng *et al.*, 1997; Ceneviva *et al.*, 1998). Overexpression of iNOS did not inhibit endothelial cell proliferation and viability, but inhibited endotoxin-induced apoptosis in these cells by reducing caspase-3-like protease activity, and possibly via induction of hsp70, heme oxygenase-1, and metallothionein. In contrast, recombinant iNOS transduction by plasmid lipofectin in rat and human smooth muscle cells can lead to a marked inhibition of DNA synthesis, as well as induction of apoptosis, both being abrogated by the NOS inhibitor *N*-monomethyl-L-arginine (L-NMMA) (Iwashina *et al.*, 1998). In both porcine coronary and human aortic smooth muscle cells, adenoviral mediated eNOS gene transfer also resulted in G₀/G₁ arrest of the regular cell cycle in a cGMP-dependent manner (Sato *et al.*, 1998). These studies suggest that NO produced from NOS gene expression can protect endothelial cells against apoptosis while inhibiting smooth muscle cell proliferation, both being desirable effects in the treatment of proliferative vascular diseases.

ATHEROSCLEROSIS AND THROMBOSIS

Atherosclerosis in coronary arteries, carotid arteries, iliac-femoral arteries, aortas, and renal arteries results in conditions such as unstable angina and myocardial infarction, brain ischemia and stroke, and claudication and leg ulcers. Hypercholesterolemia and hyperhomocysteinemia are associated with impaired NO-mediated endothelium-dependent relaxation, most likely due to a combination of increased superoxide generation, decreased antioxidant capacity, and

reduced synthesis and/or increased degradation of NO (Harrison, 1997; Refsum *et al.*, 1998). Endothelial dysfunction occurs at an early stage of the disease process, which often leads to changes in endothelial redox state, activation of oxidant-sensitive transcriptional genes [e.g., monocyte chemoattractant protein-1 (MCP-1), vascular cell adhesion molecule (VCAM)], adhesion of circulating platelets and monocytes, increased accumulation of lipids in the intima, and increased contraction, migration, and proliferation of smooth muscle cells (Maxwell *et al.*, 1998). Progressive development of atherosclerotic lesions results in the formation of lipid-laden plaques that are prone to fissure, ulceration, and rupture. Thrombosis resulting from the plaque rupture in the coronary arteries plays a pivotal role in the progression from atherosclerosis to myocardial infarction. Hence, NOS gene therapy might be expected to improve endothelium-dependent vasodilation, reverse the altered endothelial redox state (thus decreasing adhesion molecule secretion and endothelial adhesiveness), suppress smooth muscle cell proliferation, and stabilize vulnerable plaques.

Both *ex vivo* and *in vivo* NOS gene transfer to atherosclerotic arteries have been studied. In thoracic aortas of cholesterol-fed rabbits and carotid arteries of Watanabe heritable hyperlipidemic rabbits (WHHL) subjected to adenoviral mediated eNOS gene transfer, recombinant eNOS expression was evident in both endothelial cells and adventitia 24 hours after transduction (Mozes *et al.*, 1998; Ooboshi *et al.*, 1998). In atherosclerotic arteries, ACh-induced endothelium-dependent relaxation was significantly improved. Consistent with these results, *in vivo* transfer of an nNOS gene to the atherosclerotic carotid artery of cholesterol-fed rabbits ameliorated the impaired endothelium-dependent vasodilation in response to ACh (Channon *et al.*, 1998). Hence, gene transfer of the constitutive NOS enhances vascular NOS activity and improves vascular relaxation in vessels with dysfunctional endothelium. Furthermore, constitutive NOS may also be better suited than iNOS in this setting because their activities are subject to regulation by Ca²⁺ and endogenous agonists (discussed later).

The feasibility of adenoviral mediated gene transfer to atherosclerotic arteries of primates and humans has also been explored (Rios *et al.*, 1995; Ooboshi *et al.*, 1998; Rekhter *et al.*, 1998; Laitinen and Yla-Herituala, 1998). Adenovirus vectors encoding a β -galactosidase and a placental alkaline phosphatase have been transferred, to atherosclerotic monkey aortas and human coronary and carotid arteries, respectively. Transgene expression was significantly higher in atherosclerotic compared to normal monkey vessels. Human coronary and carotid arteries with advanced atherosclerosis showed efficient recombinant gene expression in nonendothelial intimal cells and in macrophages and smooth muscle cells. The areas of plaque rupture and thrombus could be specific sites targeted for expression of recombinant genes. In addition, collagenase and elastase treatment increased transgene expression sevenfold in the human vessels, suggesting that the pattern of gene expression can be affected by the amount of surrounding extracellular matrix. Taken together, these studies

indicate that it is likely feasible to achieve efficient transgene expression in vessels with atherosclerosis and thrombosis.

RESTENOSIS

Restenosis refers to the late loss of lumen size relative to the original acute gain in lumen dimension induced by angioplasty. Percutaneous transluminal coronary angioplasty (PTCA) has become a mainstay in the treatment of ischemic heart disease since its introduction in 1979, with an estimated 300,000 percutaneous procedures being performed annually in the United States alone, exceeding the number of surgical revascularization procedures. In spite of significant advances in reducing the acute complications of revascularization, and application of better techniques such as the use of intracoronary stents, chronic restenosis remains a serious problem, occurring in 30 to 50% of patients (Frishman *et al.*, 1998). Restenosis reaches its peak 1 to 4 months after PTCA, perhaps reflecting an exaggerated healing response to the original balloon injury. Chemokines and mitogens secreted from the platelets, leukocytes, and other cells, induce the migration of smooth muscle cells and adventitial fibroblasts from the media and adventitia to the intima, resulting in reocclusion of the lumen. Restenosis shares some prominent features with atherosclerosis and thrombosis, including thrombus formation, intimal hyperplasia, matrix expansion and modification, and inflammatory cell infiltration within the intima and adventitia. On the basis of these concepts, the feasibility of NOS gene transfer as an intervention strategy has been investigated in a variety of animal models.

Initial *ex vivo* studies using normal pig coronary and rabbit carotid arteries have demonstrated that adenoviral mediated eNOS gene transfer results in enhanced arterial relaxation in response to acetylcholine (receptor-mediated) or calcium ionophore A23187 (non-receptor-mediated) 1 to 4 days posttransduction (Cable *et al.*, 1997a; Ooboshi *et al.*, 1997; Toyoda *et al.*, 1998). *In vivo* transduction of recombinant eNOS in a normal rabbit carotid artery model has led to similar functional effects (Kullo *et al.*, 1997b). Observations include an enhancement in ACh-induced, endothelium-dependent relaxation, a reduction in phenylephrine-induced maximal contraction, and an increase in basal cGMP formation, at 4 days posttransduction.

In agreement with data obtained from normal vessel studies, *in vivo* NOS gene delivery to a number of injured animal models has also yielded encouraging results. The pioneering study of eNOS gene transfer in a rat carotid model of neointimal hyperplasia performed by Dzau and co-workers, employed a fusigenic HVJ virus-liposome conjugate encoding a bovine eNOS cDNA (von der Leyen *et al.*, 1995). After intraluminal delivery via a catheter to the balloon-injured common carotid arteries of Sprague-Dawley rats, endothelial NO production in injured arteries was restored to normal levels 4 days after transduction, resulting in increased relaxation in response to Ca^{2+} ionophore A23187. Neointimal formation was inhibited by 70% 2 weeks after balloon injury, attributable to suppressed DNA synthesis as measured by bromodeoxyuridine (BrdU) incorporation after eNOS gene transduction.

In a more recent study in the same rat model of carotid artery injury, reduced expression of the structural protein paxillin was observed in the proliferating smooth muscle cells (Fang *et al.*, 1999). Adenoviral mediated eNOS gene transfer *in vivo* to the injured site reduced neointimal formation for up to 4 weeks, with concomitant enhancement of paxillin recovery, suggesting that NO inhibition of intimal hyperplasia may be mediated in part by the enhanced recovery of injury-induced downregulation of paxillin. In a similar model of carotid artery injury in Fischer 344 rats, a retroviral vector encoding an eNOS gene was used to transduce aortic smooth muscle cells in primary culture, followed by the seeding of transduced cells onto the luminal surface of balloon-injured arteries (L. Chen *et al.*, 1998). *Ex vivo* gene transfer had to be conducted first in cultured smooth muscle cells, due to the requirement of cell division for retroviral-mediated gene transfer. Thus retroviral vectors may have limited use for *in vivo* arterial gene transfer. Nonetheless, the seeding of cells transduced with eNOS gene at the site of arterial injury resulted in inhibition of neointimal formation of up to 37% at 2 weeks postinjury. More importantly, the phosphorylation of vasodilator-stimulated phosphoprotein (VASP), a proline-rich protein substrate of both PKG and protein kinase A (PKA) and a participant in actin filament formation in platelets, endothelial cells, and smooth muscle cells, was significantly enhanced in both eNOS transduced cells and the seeded vessels. Since carotid artery injury results in a decrease in VASP phosphorylation *in vivo* (L. Chen *et al.*, 1998), increased VASP phosphorylation following recombinant eNOS expression may play an important role in the suppression of smooth muscle proliferation.

More recently, adenoviral mediated eNOS gene transfer to rat carotid artery and to pig coronary artery after balloon injury has been studied *in vivo* (Janssens *et al.*, 1998; Varrenne *et al.*, 1998). Catheter-mediated instillation of vector resulted in efficient eNOS transgene expression in both models, resulting in significant reductions of intima-to-media ratios, approximately 70% in rat carotid artery at 2 weeks and 25% in pig coronary artery at 4 weeks postinjury. The discrepancy in the degree of reduction of intimal hyperplasia in these studies may be due to the viral titers used, as the viral dose applied to the rat carotid artery (3×10^{10} pfu/ml) was 20 times more than that used in the pig coronary artery (1.5×10^9 pfu/ml).

An alternative method to increase localized vessel wall generation of NO is use of adenoviral-mediated iNOS gene transfer. This has also been investigated in rat carotid artery and pig iliac artery models following balloon angioplasty (Shears *et al.*, 1998). A very low dose of adenoviral vector encoding iNOS (2×10^6 pfu) delivered to the rat carotid artery resulted in a near complete reduction (>95%) in neointimal formation up to 6 weeks postinjury. In the pig iliac artery, a higher viral dose (5×10^8 pfu) led to a >50% decrease of intimal hyperplasia. This remarkable degree of suppression of restenosis was observed in both models when gene transfer was initiated shortly after balloon injury. However, iNOS gene transfer did not result in regression of

performed neointimal lesions when gene transfer was carried out several days after balloon injury. Thus, expression of recombinant NOS may function to inhibit leukocyte and platelet adherence to the injured vessel while simultaneously promoting endothelial regrowth and inhibiting smooth muscle cell proliferation. It is conceivable that the initiation of cellular proliferative events can be effectively suppressed with recombinant iNOS expression, and gene therapy during the early stage of vessel injury may thus become a determining factor for a successful outcome. Transfer of an iNOS gene in this setting may be advantageous over eNOS transduction since a substantially lower amount of virus encoding iNOS may be needed to produce a therapeutic effect. This would decrease the likelihood of vector-induced cytotoxicity.

In addition to luminal delivery, successful *in vivo* eNOS gene transduction has also been achieved using adventitial delivery (Kullo *et al.*, 1997c). Here, the vector was instilled into the periarterial sheath at a final concentration of 10^{10} pfu/ml after surgical isolation of the carotid artery. Ca^{2+} -dependent eNOS enzymatic activity and cGMP levels were increased 4 days after gene transfer, indicating the expression of functionally active recombinant eNOS. Maximal contraction to phenylephrine was reduced and relaxation to Ca^{2+} ionophore A23187 was augmented. The adventitial response to arterial injury is also a determinant of intimal hyperplasia and restenosis. Balloon injury results in increased adventitial proliferation in which adventitial fibroblasts differentiate into myofibroblasts, migrate into the intima, and contribute to chronic arterial narrowing and restenosis (Zalwski and Shi, 1997). Targeting recombinant eNOS to adventitial fibroblasts with resulting increase in adventitial NO production in this setting may also prevent restenosis by inhibiting cellular proliferation and vasoconstriction.

Cerebral Vasospasm

Chronic cerebral vasospasm is a major cause of morbidity and mortality in patients with subarachnoid hemorrhage. It is a state of delayed onset of focal or diffuse narrowing of the major cerebral arteries 4–12 days after subarachnoid hemorrhage, resulting in cerebral ischemia and neurological deficits (Macdonald, 1997; Brown and Wiebers, 1998). The spastic cerebral arteries do not respond well to the currently available vasodilators and calcium channel blockers. Impairment of NO production and/or vasodilator function is an important mechanism associated with the pathogenesis of cerebral vasospasm (Sobey and Faraci, 1998; Faraci and Heistad, 1998), accompanied by decreased eNOS mRNA level, loss of nNOS immunoreactivity, and diminished cGMP formation. Consequently, experimental vasospasm can be alleviated by intravenous administration of nitroglycerin (a nitrovasodilator which releases NO within cells), intracarotid infusion of NO, intrathecal injection of NO donors, or restoration of endogenous NO production in arterial wall by administration of L-arginine and superoxide dismutase. However, the short half-life of NO and the unwanted effects of

NO donor agents (e.g., hypotension) limit their clinical usefulness. In contrast, the administration of an adenoviral vector with functional expression of recombinant eNOS in cerebral arteries raises the possibility of providing continuous NO supply to the underlying smooth muscle cells. Cerebral vasospasm usually occurs between 4 and 12 days after subarachnoid hemorrhage and since it is a transient phenomenon, adenoviral vector-mediated transfer of recombinant eNOS gene may be useful in this setting for its transient nature.

In contrast to gene transfer to the peripheral vascular bed, *in vivo* gene delivery to the cerebral vasculature has unique problems. A segment of cerebral artery cannot be occluded in order to allow localized gene delivery due to problems with brain ischemia. One approach is to deliver genes to the perivascular site via the cerebrospinal fluid (CSF) (Heistad and Faraci, 1996). Such an approach is attractive since cerebral blood flow need not be interrupted as in luminal delivery of recombinant DNA. Adenovirus-mediated gene transfer to cerebral arteries can be achieved by vector injection into the CSF via the cisterna magna, either under normal conditions or in the presence of cisternal blood (Ooboshi *et al.*, 1995; Muhonen *et al.*, 1997). Consistent with these concepts, adenoviral vectors encoding eNOS gene have more recently been delivered *ex vivo* and *in vivo* into canine cerebral blood vessels (A. F. Y. Chen *et al.*, 1997a,b). Recombinant eNOS protein is known to be localized in the adventitial fibroblasts of major cerebral arteries 24 or 72 hours after *in vivo* gene delivery, demonstrated by eNOS immunohistochemical staining and electron microscopy immunogold labeling. Bradykinin-induced relaxation was significantly augmented in eNOS- but not β -galactosidase reporter gene-transduced cerebral arteries, with a concomitant increase in cGMP production. The augmented relaxations after gene transfer were adventitia dependent, as the transgene was not expressed in smooth muscle cells, and removal of endothelial cells did not affect relaxation (A. F. Y. Chen *et al.*, 1997a, Tsutsui *et al.*, 1998). In addition, *ex vivo* eNOS gene transfer to spastic canine cerebral arteries following subarachnoid hemorrhage resulted in enhanced expression of recombinant eNOS protein, with partial restoration of impaired NO-mediated relaxations via adventitial NO production (Onoue *et al.*, 1998). Thus, functional eNOS transgene expression in adventitial fibroblasts results in the alteration of cerebral vasoreactivity in normal and spastic cerebral arteries.

Although cerebrovascular gene transfer has been studied *ex vivo* and *in vivo* in various animal species, only relatively recently has information regarding the feasibility of transgene expression in human cerebral blood vessels become available (A. F. Y. Chen *et al.*, 1998b,c). Human pial arteries, obtained from surgically resected temporal lobectomy specimens for intractable epilepsy, were susceptible to adenoviral vector-mediated *ex vivo* gene transfer. The level of recombinant protein expression in human pial arteries is comparable to those in porcine cerebral vessels, but significantly less than those in canine or rabbit arteries. Expression of adenoviral receptor mRNA can also be detected in fresh human pial arteries as well as basilar and middle cerebral arteries

obtained post mortem. Hence, adenoviral vector-mediated gene transfer to human cerebral arteries is feasible, and adenoviral receptor CAR is present in these vessels. Furthermore, heterogeneity exists in transgene expression between human and animal cerebral arteries.

Graft Vasculopathy

VEIN GRAFT STENOSIS

The internal mammary artery (IMA) is the conduit of choice for myocardial revascularization. However the greater saphenous vein is most commonly used in this role due to its availability and versatility in reaching distal coronary branches that cannot be bypassed with the IMA. However, 12 to 20% of saphenous vein coronary artery bypass grafts occlude during the first postoperative year and subsequent risk of graft occlusion is approximately 4% per year (FitzGibbon *et al.*, 1986). Early graft attrition, exclusive of technical failure, is associated with luminal thrombosis, whereas subsequent failure of saphenous vein grafts is due to fibrointimal hyperplasia and atherosclerosis.

Preservation or augmentation of NO production in bypass vein conduits may serve as a potential molecular approach to reduce early and long-term vein graft occlusion. As NO is known to inhibit many of the putative processes involved in graft failure such as thrombus formation and smooth muscle cell proliferation, NOS overexpression may decrease the rate of occurrence of this problem.

The first successful eNOS gene transfer to human saphenous veins using an adenoviral vector was reported (Cable *et al.*, 1997b). Recombinant eNOS was detected in the adventitia and endothelium 48 hours after *ex vivo* gene transfer, resulting in augmented relaxation to Ca^{2+} ionophore A23187 and concomitant increase in NO_2 production. This approach is particularly attractive because gene transfer can be readily achieved between the time frame of tissue harvest and the coronary bypass procedure. Eventually, it may be used to improve the patency rate in the clinical setting.

To assess possible therapeutic effects of eNOS gene transfer on late graft failure, *in vivo* eNOS gene transfer has been carried out in autologous femoral vein grafts prior to implantation to ipsilateral femoral arteries in a dog model (Matsumoto *et al.*, 1998). Increased local NO production, as a result of recombinant eNOS expression mediated by HVJ virus-liposome conjugate, inhibited more than 50% of intimal hyperplasia in the vein grafts with poor runoff 4 weeks after the operation. Augmentation of local NO via NOS gene transfer may become a feasible means to prevent late graft failure.

ARTERIAL GRAFT VASOSPASM

Radial arteries represent another choice for coronary artery bypass because they are relatively resistant to atherosclerosis compared with autogenous vein grafts. However, radial artery grafts are prone to developing arterial spasm, partially due to a locally active renin-angiotensin system in these vessels (Chester *et al.*, 1998). Although improved drug

therapy for arterial spasm is now available, vasospasm still occurs in 5 to 10% of radial artery grafts. Vasospasm of radial artery bypass grafts can cause hypoperfusion, stasis, graft thrombosis, and subsequent myocardial ischemia in early and late postoperative periods. Augmentation of NO production in radial artery conduits via NOS gene transfer can provide an effective means to antagonize the thrombotic and proliferative events, hence improving early and long-term patency results in the postoperative period.

Efficacious inhibition of radial artery contraction after adenoviral mediated gene transfer of eNOS was reported more recently (Cable *et al.*, 1998). Human radial arteries expressed recombinant eNOS protein 40 hours after transduction. Both KCl- and prostaglandin $\text{F}_{2\alpha}$ -induced contractions were reduced by more than 50% in transduced arteries compared to normal control vessels. These results suggest that adenoviral-mediated transfer of eNOS may exert an important role in prevention of radial artery graft vasospasm in future clinical applications.

ALLOGRAFT ATHEROSCLEROSIS

The development of atherosclerosis in allograft transplants is a principal cause of allograft dysfunction and late death in cardiac transplant recipients (Ardehali, 1995). In more recent years, allograft vasculopathy has replaced acute rejection as the most common cause of graft loss following cardiac transplantation (Ventura *et al.*, 1995; Russell *et al.*, 1995). The early immune-mediated upregulation of endogenous iNOS expression in arterial grafts may partially protect allografts from the development of atherosclerosis (Akyurek *et al.*, 1996). However, immunosuppressive agents commonly used for reducing allograft rejection, such as cyclosporine A, often block endogenous iNOS gene expression and accelerate the atherosclerotic process.

Gene transfer of recombinant iNOS was tested in a rat aortic allograft transplant model (Shears *et al.*, 1997). Transduction of aortic allografts in donor rats with iNOS gene at a low viral titer (10^7 pfu/ml) inhibited the development of atherosclerosis 4 weeks after allograft transplantation. Unlike endogenously expressed iNOS, transgene expression was not inhibited by cyclosporine A since the CMV-driven promoter of the adenoviral vector was not subjected to transcriptional inhibition. Thus, iNOS overexpression by a constitutively driven potent promoter may avoid immunosuppressive-related downregulation and may have a beneficial therapeutic effect in this otherwise untreatable complication.

Heart and Lung Transplantation

Heart or lung transplantation has become a viable option for the treatment of end-stage cardiac or pulmonary disease in selected patients. Despite advances in surgical techniques and organ preservation, graft and recipient survival are suboptimal and retransplantation is seldom an option. Allograft rejection and transplant vasculopathy are major causes of morbidity and mortality after clinical heart or lung transplantation. The major complications influencing the long-term

survival rate are allograft arteriosclerosis in the transplant heart and obliterative bronchiolitis in the transplant lung, respectively. In both cases, cell proliferation and fibrosis are the central components contributing to narrowing and occlusion of coronary arteries and luminal obliteration of the terminal airways. NO produces potent vasodilation and bronchodilation and reduces platelet aggregation and leukocyte adhesion, all of which are advantageous in combating the process of vasculopathy in the transplanted organs. In keeping with this notion, inhaled NO has been used in transplant heart or lung animal models and humans with beneficial effects (Auler *et al.*, 1996; Meyer *et al.*, 1998). NOS gene transfer to the allograft heart or lung may be an ideal alternative, especially because there is a delay of as much as 4 hours from the time of organ retrieval to transplantation, a time when the donor organ could be subjected to NOS gene transfer.

Studies have demonstrated the feasibility of gene transfer to the transplanted heart and lung with adenoviral vectors. The intracoronary administration of the virus has resulted in widespread transgene expression in cardiac myocytes, coronary endothelial cells, and interstitial fibroblasts in a model of abdominal heterotopic heart transplantation in syngeneic rats with or without immunosuppression (Yap *et al.*, 1997; Pellegrini *et al.*, 1998). In a syngeneic rat model of orthotopic single-lung transplantation, bronchial infusion of adenoviral vectors caused transgene expression in pneumocytes and alveolar macrophages (Jeppsson *et al.*, 1998a). More recently, transbronchial gene delivery of eNOS in the same animal model of lung transplant resulted in recombinant eNOS protein expression in more than 75% pneumocytes 4 days following transduction (Jeppsson *et al.*, 1998b). Moreover, Ca^{2+} dependent eNOS enzymatic activity was increased dramatically in eNOS transduced lungs. Gene transfer of recombinant eNOS may thus be employed to inhibit allograft arteriosclerosis in transplanted hearts and obliterative bronchiolitis in transplanted lungs.

Hypertension

PULMONARY HYPERTENSION

Pulmonary hypertension is a disease with high morbidity and mortality which currently has limited therapeutic options. Specific diseases in this category include primary pulmonary hypertension and hypoxic chronic pulmonary hypertension. Inhalation of low concentrations (i.e., <80 ppm) of gaseous NO has been used to dilate pulmonary vasculature and improve the perfusion of ventilated lung, resulting in alleviation of the adult respiratory distress syndrome (Rossaint *et al.*, 1993) and reduced hypoxic vasoconstriction in newborns (Roberts *et al.*, 1997). Since reduced expression of eNOS and diminished endothelium-dependent relaxation are involved in pulmonary hypertension (Giaid and Saleh, 1995), transfer of the eNOS gene may also reduce vascular resistance of the pulmonary circulation and provide a local therapeutic approach to pulmonary hypertension.

Adenoviral-mediated human eNOS gene delivery using aerosolization has been reported in an acute hypoxic rat

model of pulmonary hypertension (Janssens *et al.*, 1996). Recombinant eNOS was expressed in alveoli and small and medium-sized pulmonary vessels with increased eNOS activity and cGMP levels. Pulmonary arterial pressure was reduced to the control level without affecting systemic blood pressure. Thus, NOS gene transfer to the airways via aerosolization may be a potential therapeutic approach for pulmonary hypertension.

ESSENTIAL HYPERTENSION

Essential hypertension affects approximately 20% of the adult population and has a multifactorial origin arising from an interaction between susceptible genes and environmental factors. A dysfunctional L-arginine–NO pathway including a defect in eNOS gene has been implicated in the pathogenesis of hypertension (Arnal *et al.*, 1995; Huang *et al.*, 1995). A more recent study has investigated the effect of eNOS gene transfer to spontaneously hypertensive rats (SHR), using a human eNOS plasmid DNA driven by a CMV promoter (Lin *et al.*, 1997). A single injection of the eNOS plasmid DNA through the tail vein of SHR rats caused a significant reduction of systemic blood pressure for 6 weeks, and a second injection maintained the effect up to 12 weeks. In this experiment, increased NO production was determined as increased urinary and serum $\text{NO}_2^-/\text{NO}_3^-$ content as well as increased cGMP levels in the urine and aorta. Somatic delivery of the eNOS gene using such a nonviral vector may be both safe and useful as a means for the treatment of essential hypertension.

Diabetes Mellitus

Accelerated atherosclerosis is a major cause of morbidity and mortality in patients with diabetes mellitus. Sustained elevation of serum glucose causes nonenzymatic glycation and oxidation of proteins and lipids, resulting in the accumulation of irreversibly formed advanced glycation end products (AGEs). The AGEs in diabetic vascular tissues are directly toxic to endothelial cells, leading to vascular dysfunction including impaired NO-mediated endothelium-dependent relaxation, vascular matrix expansion, and athero- and glomerulosclerosis. In addition, hyperglycemia or hyperinsulinemia can induce superoxide anion generation in endothelial cells, which may be mediated by specific isoforms of protein kinase C (Maxwell *et al.*, 1998).

Currently, studies are being conducted in animal models of diabetes mellitus to assess the effect of recombinant eNOS expression on the impairment of endothelium-dependent relaxation. In a rabbit model of alloxan-induced diabetes, stable hyperglycemia (>400 mg/dl) can be achieved, resulting in decreased ACh-induced relaxation in the aorta. Adenoviral-mediated eNOS gene transfer to the vessels *ex vivo* can result in eNOS transgene expression in both endothelial cells and the adventitial layer 24 hours following transduction. In this experiment, gene transfer of eNOS to the diabetic rabbit aortic rings augmented ACh-mediated relaxation, but did not reverse abnormal contraction in response to higher concentrations of ACh in diabetic vessels (Zanetti *et al.*, 1999).

Ischemic, Congestive, or Hypertrophic Heart Disease

NO is an important modulator of cardiac function, coronary vascular function, and myocardial metabolism (Drexler, 1998; Ingwall and Kelly, 1998). Although NO is thought to participate in events following reperfusion of the heart, as either a beneficial or a detrimental factor (Curtis and Pabla, 1997), compelling evidence suggests that diminished NO bioactivity causes constriction of coronary arteries, contributes to provocation of myocardial ischemia, and facilitates vascular inflammation with oxidation of lipoproteins. In both human and animal models of congestive heart failure, impaired endothelial NO release is observed in large coronary arteries and microvessels, which is attributable to reduced eNOS gene expression (Smith *et al.*, 1996). Reduced NO production can result in diastolic dysfunction (i.e., impaired relaxation and increased ventricular preload) and altered myocardial energy metabolism (Recchia *et al.*, 1998). Consequently, the therapeutic properties of NO donor agents (e.g., organic nitrates) in heart failure are based, to some extent, on the reduction of ventricular preload (Elkayam, 1996). Under these circumstances, eNOS gene transfer might be useful as an approach to assess the possibility of reversing myocardial endothelial dysfunction by enhancing the production and release of NO.

The direct *in vivo* transfer of the eNOS gene to the heart has been reported (Shin *et al.*, 1996; Kawaguchi *et al.*, 1997). HVJ (Sendai virus)-coated liposomes containing human eNOS cDNA were percutaneously injected into myocytes of the left ventricular wall in normal Wistar rats. Morphological analysis of transduced myocytes revealed cell shrinkage, loss of myofilaments, and mitochondrial swelling and accumulations only when the high dose of HVJ-liposomes encoding eNOS cDNA was given (i.e., 50 μ g), 1 week after transduction. This report provides the first observations of cytotoxicity directly related to recombinant eNOS-induced NO production, as β -galactosidase reporter gene expression in these cells did not cause cell death. Given the high chemical reactivity of NO, it is not unlikely that when NO is produced in large amounts following transduction, it may contribute to increased susceptibility to cell injury. In addition, the possibility of peroxynitrite involvement as a result of interaction between NO and superoxide anion could not be ruled out in this setting. Future studies of gene transfer using various NOS isoforms in different doses in the setting of heart failure may provide information on the potential therapeutic effects of NO in the failing heart.

Portal Hypertension and Cirrhosis

Portal hypertension is a major complication of cirrhosis, portal venous thrombosis, and pre- and postsinusoidal liver disorders such as schistosomiasis and veno-occlusive disease. Augmentation of intrahepatic resistance in cirrhotic liver results from fibrosis and scarring, a process involving stellate cells (i.e., a cell type with smooth muscle feature). Activated stellate cells transform into myofibroblasts, a cell type common to wound healing, which contributes to

endothelin-induced contraction in fibrous bands (Rockey, 1997). On the other hand, NO released from sinusoidal endothelial cell modulates portal pressure in response to hepatic flow, and its dysfunction may contribute to portal hypertension and facilitate the development of the hepatorenal syndrome (Shah *et al.*, 1997, 1998).

In cirrhotic liver of human and animal species, eNOS expression is reduced in sinusoidal and hepatic venular endothelial cells (Shah *et al.*, 1998). Perfusion of L-arginine reduces portal pressure in response to norepinephrine stimulation (Rockey, 1997), suggesting a protective role of endogenous NO in this state. In addition, endogenous iNOS expression by hepatocytes plays an important role in hepatocyte function and protects the liver during sepsis and ischemia reperfusion (Taylor *et al.*, 1998). NO prevents intravascular thrombosis by inhibiting platelet adhesion and neutralizing toxic oxygen radicals. It also blocks TNF- α -induced apoptosis and hepatotoxicity, perhaps in part by a thiol-dependent inhibition of caspase-3-like protease activity (Y.-M. Kim *et al.*, 1997).

Although NO has beneficial effects in the hepatic vasculature, the means to deliver NO to hepatocytes in a sustained manner are currently limited. More recently, the feasibility of NOS gene transfer was tested as an approach to deliver an intracellular source of NO in order that apoptosis in hepatocytes may be inhibited and that stellate cell contractility in cirrhosis may be decreased (Kim *et al.*, 1998; Tzeng *et al.*, 1998; Fevery *et al.*, 1998). Adenoviral-mediated iNOS gene transfer resulted in sustained NO production and protected hepatocytes from spontaneous and TNF- α -induced apoptosis in these cells (Tzeng *et al.*, 1998). The caspase-3-like protease activity associated with apoptosis was suppressed by iNOS gene transfer. In CCl₄-induced cirrhotic rats, an injection of adenoviral vector encoding eNOS into the portal vein resulted in recombinant eNOS expression in sinusoidal-lining endothelial cells (Fevery *et al.*, 1998). Portal pressure of the cirrhotic rats was significantly reduced 4 days after *in vivo* eNOS gene delivery. Targeted delivery of the NOS gene to selected cell types of the liver may hold promise as a means to treat portal hypertension and cirrhosis.

Impotence

NO plays a pivotal role in the regulation of human reproductive function and is a physiological mediator of penile erection (Rosselli *et al.*, 1998). NO mediates normal erection by relaxing the cavernosal smooth muscle of the penis. Although neuronal NO produced by nNOS of the cavernosal nerve terminals plays a major role in the process (Rajfer *et al.*, 1992; Burnett *et al.*, 1992), eNOS and iNOS are also present in smooth muscle and endothelial cells of corpus cavernosum and penile blood vessels, providing additional sources for endogenous NO production (Rajasekaran *et al.*, 1998). Erectile dysfunction due to the inability of the cavernosal smooth muscle to undergo complete relaxation is manifested in aging and in a number of diseases such as diabetes mellitus (Vernet *et al.*, 1995). Augmentation of NO levels by various methods has been tested in animal models and in

clinical trials of human impotence (Wegner *et al.*, 1995; Moody *et al.*, 1997). The use of NO donor agents and inhibitors of cGMP breakdown, while beneficial in ameliorating impotence, can cause side effects. Localized and targeted augmentation of NO release via NOS gene transfer to cavernosal smooth muscle and endothelial cells of penile vessels may represent an alternative future means for such treatment.

To this end, the possibility of whether the stimulation of penile NOS expression by local induction or gene transfer may mitigate erectile dysfunction in an aged rat model has been investigated (Garban *et al.*, 1997). Following the injection of a mix of iNOS inducers or iNOS cDNA to the rat penis, erectile dysfunction in the aged rats was ameliorated, as measured by the erectile response to electrical field stimulation of the cavernosal nerve. Future studies with targeted local gene transfer of different NOS isoforms to the aged animal and human penile tissue will help to shed more light on the feasibility of gene therapy for erectile dysfunction.

Wound Healing

NO plays a critical role in human skin physiology and pathophysiology. It serves as an autocrine and paracrine mediator in maintaining normal skin homeostasis and in promoting the wound healing process (Weller, 1997; Bruch-Gerharz *et al.*, 1998a,b). NO is produced in a variety of specialized human skin cells including keratinocytes (Baudoin and Tachon, 1996; Shimizu *et al.*, 1997; Roméro-Graillet *et al.*, 1997), melanocytes (Roméro-Graillet *et al.*, 1996, 1997; Jackson *et al.*, 1998), Langerhans cells (Qureshi *et al.*, 1996; Morhenn, 1997), fibroblasts (Wang *et al.*, 1996; Schaffer *et al.*, 1997a), and endothelial cells (Bull *et al.*, 1996).

Wound healing is a well-orchestrated and highly coordinated process involving angiogenesis, collagen synthesis, and re-epithelialization (Clark, 1996). Compelling evidence indicates that NO plays a key role in wound repair. Production of nitrite and nitrate, the stable NO metabolites, is elevated early and transiently in fluid obtained from sponges implanted in subcutaneous wounds (Albina *et al.*, 1990), while urinary nitrate excretion increases in a sustained manner after excisional wounding (Smith *et al.*, 1991) and burn injury (Becker *et al.*, 1993; Carter *et al.*, 1994). The presence of nitrite and nitrate, as an indicator of NOS activity, is directly correlated with collagen deposition within the wound and by dermal fibroblasts in culture (Schaffer *et al.*, 1996, 1997a–c). Furthermore, iNOS and GTP-cyclohydrolase I, the rate-limiting enzyme for the synthesis of NOS essential cofactor BH₄, are expressed in coordination and colocalized in keratinocytes and epithelium during the process of cutaneous wound repair in mice (Frank *et al.*, 1998a,b). Finally, a deficiency of the L-arginine–NO pathway under various diseased conditions such as diabetes and steroid treatment contributes to impaired wound healing (Bulgrin *et al.*, 1995; Schaffer *et al.*, 1997c; Veves *et al.*, 1998).

Conversely, NO promotes processes central to wound healing such as angiogenesis (Ziche *et al.*, 1994, 1997), migration, and proliferation of fibroblasts (Schaffer *et al.*, 1997a), epithelial cells (Noiri *et al.*, 1996), and endothelial

cells (Papapetropoulos *et al.*, 1997; Parenti *et al.*, 1998). Indeed, systemic L-arginine administration improves wound healing in normal individuals (Barbul *et al.*, 1990) and in aged individuals with impaired wound healing (Kirk *et al.*, 1993), and topical application of a NO donor agent accelerates closure of excisional wounds in rats (Shabani *et al.*, 1996). In addition, NO formation as a direct result of cutaneous wounding induces expression of vascular endothelial growth factor (VEGF) in mice (Frank *et al.*, 1998a), and the angiogenesis effect of VEGF is mediated in part by NO (Ziche *et al.*, 1994, 1997; Papapetropoulos *et al.*, 1997). By contrast, nonspecific NOS inhibitors applied to the surface of the wound (Bulgrin *et al.*, 1995) or given systemically (Schaffer *et al.*, 1996) retard wound healing.

The possibility that recombinant NOS expression may promote endothelial regeneration after injury (hence accelerating vascular healing) has been investigated in iNOS knockout mice subjected to excisional wounding (Yamasaki *et al.*, 1998). Wound closure was delayed by 31% in iNOS knockout mice compared with wild-type animals, and the delay in wound healing was also observed in wild-type mice given N⁶-(iminoethyl)-L-lysine (NIL), a relatively selective iNOS inhibitor. Delayed wound healing in iNOS-deficient mice was completely reversed by adenoviral-mediated iNOS gene transfer at the time of wounding. In male Sprague-Dawley rats that received a longitudinal dorsal midline incision, plasmid-mediated iNOS gene transfer with or without cationic liposomes resulted in recombinant iNOS expression and augmented NO production, which preceded an increase in collagen synthesis and accumulation (Thornton *et al.*, 1998). The results from these studies suggest that iNOS gene transfer may improve wound-healing processes in iNOS-deficient states such as diabetes (Schaffer *et al.*, 1997b) and during steroid treatment (Bulgrin *et al.*, 1995).

Interactions between Recombinant NOS Protein and Host Environment

Individual isoforms of endogenous NOS protein are regulated at transcriptional, translational, and posttranslational levels through multiple and complex cellular processes (Sessa, 1994; Sase and Michel, 1997). The Ca²⁺-binding protein calmodulin interacts with all three NOS isoforms as its binding is required for their enzymatic activity. A variety of endogenous proteins can interact with nNOS, including 1-syntrophin, postsynaptic density proteins (PSD) 93 and 95, and the mammalian homolog of dynein light chain protein inhibitor of nNOS (PIN) (Christopherson and Bredt, 1997). The proteins can each bind with nNOS and localize it to specific subcellular region of myocytes or neurons. The heat shock protein 90 (hsp90) is involved in the regulation of both nNOS and eNOS activities, in addition to its role in protein folding and maturation processes (García-Cardena *et al.*, 1998; Bender *et al.*, 1999). Hsp90 has been shown to associate with eNOS *in vitro* and nNOS *in vivo* on activation by different agonists. Consequently, the binding of hsp90 to

eNOS or nNOS augments the activation process of the two constitutive isozymes. The inducible NOS was previously thought to be regulated primarily at the level of transcription, but most recent evidence indicates that iNOS can be modulated negatively at the posttranscriptional level by a cytosolic protein, kalirin (Ratovitski *et al.*, 1999). Likewise, different isoforms of recombinant NOS proteins may also be subjected to modulation via their interaction with various endogenous proteins and agonists. The tissue-specific regulation of recombinant NOS proteins may exert significant influences on the functionality and effects in different cardiovascular beds following NOS gene transfer.

Recombinant NOS and Ca^{2+} and Caveolin

Constitutive NOS functions are highly regulated by plasmalemmal caveolae, the small invaginations of the plasma membrane involved in the regulation of multiple signal transduction pathways (Michel and Feron, 1997; Anderson, 1998; Shaul and Anderson, 1998). Endothelial NOS is localized in caveolae of endothelial cells and cardiac myocytes through association with the caveolae integral-membrane structural proteins caveolins-1 and -3, respectively. Caveolin proteins play a key role in eNOS sequestration after the enzyme is palmitoylated and exert a direct inhibitory effect on eNOS activity (Michel and Feron, 1997), through a 20-amino acid region within the caveolin sequence named caveolin scaffolding domain (Li *et al.*, 1996). This inhibition can be completely reversed via a reciprocal regulatory cycle through which caveolin proteins interact with Ca^{2+} -calmodulin complex (Michel and Feron, 1997). In resting endothelial cells, the association between eNOS and caveolin suppresses eNOS enzyme activity. After agonist activation, the increase in intracellular Ca^{2+} promotes calmodulin binding to eNOS and the dissociation of caveolin from eNOS. The activated eNOS-calmodulin complex synthesizes NO until intracellular Ca^{2+} decreases to the point that calmodulin dissociates and the inhibitory eNOS-caveolin complex reforms. Moreover, the localization of eNOS in caveolae may also optimize NO production via a caveolar complex in which eNOS and an arginine transporter protein are colocalized and from which the direct transfer of extracellular arginine to membrane-bound eNOS may be facilitated (McDonald *et al.*, 1997). In addition, a number of G protein-coupled receptors such as muscarinic M_2 , bradykinin B_2 , and endothelin receptors are targeted to caveolae on agonist binding (Anderson, 1998; Shaul and Anderson, 1998). Activation of these receptors in caveolae promotes eNOS depalmitoylation that may lead to the release and translocation of functional eNOS from caveolae to the cytosol.

Adenoviral-mediated eNOS gene transfer to cerebral arteries not only results in recombinant eNOS expression in caveolae of adventitial fibroblasts, but also causes augmented arterial relaxation induced by bradykinin in the absence of endothelial cells (A. F. Y. Chen *et al.*, 1997a; Tsutsui *et al.*, 1998). Bradykinin receptors are present on fibroblasts, and activation of these receptors leads to both extracellular calcium influx and intracellular calcium release

(Byron *et al.*, 1992; Baumgraten *et al.*, 1995). Hence, the adventitial fibroblasts of arterial walls are well equipped with the machinery for receptor-mediated, caveolae-associated activation of recombinant eNOS protein.

Neuronal NOS is similar to eNOS structurally (i.e., sharing >60% amino acid sequence identity) and in the requirement of Ca^{2+} for activity. It is expressed not only in neurons, but also in skeletal muscle where it is involved in the regulation of contractility (Christopherson and Bredt, 1997). Neuronal NOS in the skeletal muscle dystrophin complex interacts not only with 1-syntrophin but also with caveolin-3, and the latter interaction serves to inhibit nNOS catalytic activity (Venema *et al.*, 1997). Thus, the capacity to interact with caveolin proteins seems to be a general property of the Ca^{2+} -dependent NOS enzymes. Recombinant nNOS may also be targeted to and similarly modulated by caveolin-3 after nNOS gene transfer. In contrast, iNOS is unlikely to be targeted to caveolae or regulated by interactions with caveolin, since it binds calmodulin avidly, and the binding of caveolin and calmodulin are mutually exclusive.

The interactions between caveolin and constitutive NOS, but not iNOS, may thus play a critical role in the regulation of recombinant NOS function, and should be considered when choosing an isoform of NOS for gene transfer. It is hoped that future comparative studies of isoform-specific NOS gene expression in different vascular beds and in different animal models will shed more light on the interaction of recombinant NOS with caveolae-associated proteins.

Recombinant NOS and Oxygen Free Radicals

NO synthesis requires optimal supply of both L-arginine, the precursor, and tetrahydrobiopterin (BH_4), an essential cofactor of NOS (Katusic, 1996; Mayer and Hemmens, 1997). L-arginine facilitates NO production by competing as a substrate, either with a potent endogenous NOS inhibitor N^G , N^G -dimethyl-L-arginine (ADMA) produced in brain and other tissue, or with molecular oxygen to reduce the formation of superoxide anion. On the other hand, BH_4 participates in nicotinamide adenine dinucleotide phosphate (NADPH)-dependent oxygen activation during NO synthesis and its depletion leads to uncoupling of oxygen reduction and arginine oxidation, resulting in superoxide production via the heme moiety of NOS (Kinoshita *et al.*, 1997; Shimizu *et al.*, 1998; Werner *et al.*, 1998). Thus, in the absence of adequate L-arginine or BH_4 , NOS can act as a superoxide-generating enzyme.

The degradation of NO *in vivo* largely results from its interaction with superoxide anion which inactivates NO rapidly to form peroxynitrite, a potent oxidant implicated in vascular injury involving protein nitrosylation and DNA damage (Wever *et al.*, 1998). In addition to its formation by NOS in the absence of L-arginine or BH_4 , superoxide can also be produced from two other important sources: NADH/NADPH oxidase or arachidonic acid in the cyclooxygenase pathway (Harrison, 1997).

The consequence of the NO-superoxide reaction depends in part on the ratio of NO to superoxide. Under most

physiological conditions, NO plays a protective role in the cardiovascular system through its interactions with superoxide and NADPH oxidase (Harrison, 1997). NO inactivates NADPH oxidase by inhibiting its assembling process in neutrophils (Fujii *et al.*, 1997). Peroxynitrite formed by superoxide and NO mimics the effects of NO by inhibiting platelet aggregation and leukocyte adhesion to endothelial cells, producing vasodilation, and even acting as a NO donor agent (Wever *et al.*, 1998). On the other hand, NO may exacerbate the injuries by inducing peroxynitrite formation in diseases such as atherosclerosis and myocardial ischemia–reperfusion in which superoxide production may be enhanced (Curtis and Pabla, 1997). Excessive superoxide formation with perturbed NO synthesis in such cardiovascular diseases may result in accumulation of larger amounts of peroxynitrite and subsequent formation of highly toxic hydroxyl radicals (Katusic, 1996). Under these circumstances, overexpression of recombinant NOS may not necessarily be beneficial.

Future Prospects

The critical and detailed roles that NO plays in the cardiovascular system in health and disease have been reported extensively since the 1980s. As detailed knowledge regarding the function and regulation of individual NOS isoforms in disease is gained, therapeutic potentials of NO have gradually been explored. To this end, the feasibility of recombinant NOS gene transfer to various cardiovascular beds has now been established *ex vivo* and *in vivo* in a number of animal models and human tissues. Localized vascular NOS gene expression is advantageous over NO supplementation by either NO or NO donor agents. However, several obstacles must be overcome before NOS gene therapy can enter the clinical arena. In addition to choosing an appropriate isoform of NOS for gene transfer to specific vascular cells, a major issue is the limitations of currently available vectors. Another clinically formidable obstacle is finding a means to effectively deliver the vectors to the vessel wall. Improvements in both vector design and *in vivo* gene delivery methods are therefore still required prior to clinical application of recombinant NOS genes in therapy. Finally, caution is necessary regarding NOS overexpression in situations where the adverse consequences of NO–free radical interactions may outweigh the direct benefits of NO alone.

University of Antwerp
Wilrijk, Belgium*

THE REGULATORY FUNCTIONS OF THE ENDOTHELIUM ARE CHANGED BY INJURY OR ACTIVATION. DYSFUNCTION OF THE ENDOTHELIUM CAN BE DEFINED AS AN IMBALANCE BETWEEN RELAXING AND CONTRACTING FACTORS, BETWEEN PRO- AND ANTI-COAGULANT MEDIATORS, OR BETWEEN GROWTH-INHIBITING AND GROWTH-PROMOTING SUBSTANCES. THIS CHAPTER FOCUSES ON THE ROLE OF THE L-ARGININE-NITRIC OXIDE (NO) PATHWAY IN VASCULAR ENDOTHELIAL DYSFUNCTION. SEVERAL DISEASES, SUCH AS ATHEROSCLEROSIS, HYPERCHOLESTEROLEMIA, HYPERTENSION, DIABETES, AND HEART FAILURE, AS WELL AS AGE AND GENDER ARE ACCOMPANIED BY ALTERATIONS IN THIS PATHWAY, BOTH IN EXPERIMENTAL ANIMAL MODELS AND IN HUMANS. THE MECHANISMS OF NO-RELATED VASCULAR ENDOTHELIAL DYSFUNCTION UNDER THESE CONDITIONS WILL BE DISCUSSED, TOGETHER WITH SOME ASSOCIATED THERAPEUTIC ASPECTS.

Introduction

The regulatory functions of the endothelium are changed by injury or activation. Dysfunction of the endothelium has been defined as an imbalance between relaxing and contracting factors, between pro- and anticoagulant mediators, or between growth-inhibiting and growth-promoting substances (Rubanyi, 1993). This chapter will focus on the role of the L-arginine-nitric oxide (NO) pathway in vascular endothelial dysfunction. Several diseases, such as atherosclerosis, hypercholesterolemia, hypertension, diabetes, and heart failure, are accompanied by alterations of vascular NO production and/or bioavailability, both in experimental animal models and in humans. Thereby, vasoconstrictor responses to certain substances are augmented. Impaired endothelium-dependent vascular relaxation is only one manifestation of altered endothelial function. It may be associated with an increased adhesion of leukocytes or altered balance of profibrinolytic to prothrombotic activity and may

play a role in the disease process itself. However, it is not known whether impaired endothelium-dependent relaxation always reflects this more general endothelial dysfunction.

NO-Related Vascular Endothelial Dysfunction in Atherosclerosis and Hypercholesterolemia

Observations in Animals and Humans

In vessels with overt atherosclerotic pathology or in vessels from hypercholesterolemic rabbits, monkeys, and pigs with serum cholesterol levels of 600–2000 mg/dl, relaxation to acetylcholine (ACh) and other receptor-mediated (ATP, substance P, thrombin, bradykinin) inducers of NO biosynthesis is impaired (Coene *et al.*, 1985; Verbeuren *et al.*, 1986; Freiman *et al.*, 1986; Bossaller *et al.*, 1987; Harrison *et al.*, 1987; Yamamoto *et al.*, 1987; Jayakody *et al.*, 1987; Cohen *et al.*, 1988; Förstermann *et al.*, 1988; Shimokawa and Van-

houtte, 1988; Sellke *et al.*, 1990; Verbeuren *et al.*, 1990; Bult *et al.*, 1995) (Fig. 1). However, Merkel *et al.* (1990) demonstrated that even a modest elevation of serum cholesterol is sufficient to depress endothelium-dependent relaxations to carbamylcholine and to enhance vasoconstrictor responses to serotonin (5-HT). The NO defect is presumably the result, rather than the cause, of the vascular lesions, since endothelium-dependent responses are preserved in adjacent normal areas and arteries which do not develop fatty streaks (Verbeuren *et al.*, 1986; Senaratne *et al.*, 1991; Galle *et al.*, 1991). The latter findings are hard to reconcile with the proposal that hypercholesterolemia suppresses endothelial NO release (Minor *et al.*, 1990). However, one cannot exclude the possibility that progressive reduction of NO release aggravates fatty streak development (Cayatte *et al.*, 1994; Naruse *et al.*, 1994).

In most of these studies, histologic examination of the endothelium in blood vessels from cholesterol-fed animals revealed either no abnormality or only small changes in the endothelium. Endothelial cell denudation was minimal or

absent. Therefore, hypercholesterolemia and diet-induced atherosclerosis produce a functional rather than an anatomic abnormality of the endothelium (Harrison, 1994). Endothelium-mediated relaxation in the Watanabe heritable hyperlipidemic (WHHL) rabbit, an animal model of familial hypercholesterolemia (Buja *et al.*, 1983) is attenuated with progression of atherosclerosis (Kolodgie *et al.*, 1990; Ragazzi *et al.*, 1989).

The early work concerning vascular endothelial dysfunction in animals involved large conduit arteries. The resistance vasculature does not develop overt atherosclerosis. Thus, it might be possible that endothelium-dependent vascular relaxation may be normal in this segment of the circulation despite the presence of atherosclerotic lesions in larger vessels. However, it has been shown that hypercholesterolemia can also alter endothelial function in the microcirculation of rabbits, primates, and pigs (Yamamoto *et al.*, 1988; Sellke *et al.*, 1990; Kuo *et al.*, 1992). Endothelium-dependent vascular relaxations to bradykinin, ACh, and the calcium-ionophore A23187 were abnormal in resistance vessels from cholesterol-fed animals. In contrast, relaxations to the endothelium-independent vasodilators nitroprusside and adenosine were not altered in these vessels. Thus, in addition to predisposing large vessels to altered vasomotion, endothelial dysfunction in atherosclerosis may also impair neurohumoral regulation of tissue perfusion at the microvascular level (Harrison, 1994).

NO contributes importantly to resting epicardial and coronary microvascular tone. Coronary vascular dilation in response to ACh is predominantly due to increased production of NO. *In vitro* studies with isolated human coronary arteries have shown that the endothelium-dependent vasodilators ACh and substance P relax nonatherosclerotic coronary segments (Bossaller *et al.*, 1987; Förstermann *et al.*, 1988). However, in isolated atherosclerotic human coronary arteries, endothelium-dependent relaxations to ACh are abolished (Bossaller *et al.*, 1987; Förstermann *et al.*, 1988), and those to substance P (Bossaller *et al.*, 1987; Förstermann *et al.*, 1988; Chester *et al.*, 1990), histamine (Bossaller *et al.*, 1987), and bradykinin (Chester *et al.*, 1990) are partly suppressed. The response to A23187 may be completely preserved (Bossaller *et al.*, 1987) or not (Förstermann *et al.*, 1988). Some of these *in vitro* findings have been extended to the *in vivo* situation.

Ludmer *et al.* (1986) demonstrated paradoxical vasoconstriction induced by ACh both early and late in the course of coronary atherosclerosis in patients, suggesting an association of endothelial dysfunction and atherosclerosis. Furthermore, the coronary arteries of cardiac transplant patients may constrict in response to ACh even though angiographic evidence of coronary artery disease is absent (Fish *et al.*, 1987). In patients with normal coronary arteriograms and angina pectoris an impairment of endothelium-dependent vasodilation is present similar to that observed in patients with overt coronary artery atherosclerosis (Werns *et al.*, 1989; Vrints *et al.*, 1992). Using intracoronary infusions of ACh, substance P, and nitroglycerin (NTG), Bossaller *et al.* (1989) and Crossman *et al.* (1989) provided evidence that the failure of

Figure 1 Example of NO-related vascular endothelial dysfunction. The figure represents relaxation curves to acetylcholine (ACh, top graph) and the NO donor SIN-1 (bottom graph) in the thoracic aorta of rabbits exposed to a control diet (○) or a diet supplemented with cholesterol (●). In controls, ACh caused about 82% relaxation of rings contracted with phenylephrine. A cholesterol-rich diet led to both a rightward shift of the concentration-response curve and a reduction of the amplitude of the relaxation (*, different from control group, $P < 0.05$). The relaxation curve to the exogenous NO donor SIN-1 in aortic segments from hypercholesterolemic rabbits did not differ from controls, excluding the possibility that the fatty streaks developed in response to the diet interfered with the relaxing capacity of the thoracic aorta. (After Bult *et al.*, 1995.)

atherosclerotic human coronary arteries to dilate in response to ACh represents a muscarinic endothelial dysfunction. Vita *et al.* (1990) showed that patients with angiographically smooth coronary arteries and few risk factors for coronary disease tend to exhibit coronary vasodilation in response to intracoronary ACh infusion, whereas patients with the same apparently normal coronary arteries and increased risk factors show segmental coronary vasoconstriction. It has also been demonstrated that most of the angiographically normal coronary arteries in subjects more than 30 years old, as well as in patients with coronary artery disease, constrict to an intracoronary injection of ACh, as do coronary arteries with evident atherosclerosis, whereas those of younger subjects dilate in response to this agent (Yasue *et al.*, 1990). Furthermore, despite the absence of angiographic evidence of atherosclerosis, exposure to coronary risk factors is associated with reduced resting and stimulated bioavailability of NO from the human coronary circulation (Quyyumi *et al.*, 1995).

Thus, endothelial dysfunction occurs early in atherosclerosis, predating clinical disease. It has also been demonstrated that endothelial dysfunction is associated with cholesterol levels in the high normal range in humans. There was a negative correlation between total cholesterol levels and maximal endothelium-dependent vasodilation (Steinberg *et al.*, 1997). In addition, a more recent study by Lewis *et al.* (1999) demonstrated that endothelium-dependent relaxation by acetylcholine is also impaired in hypertriglyceridemic humans with normal levels of plasma low density lipoprotein (LDL) cholesterol.

Evidence of endothelial dysfunction may identify young individuals most likely to develop atherosclerosis. To assess endothelial function in large populations noninvasive approaches are preferable (Creager and Selwyn, 1997). In the human brachial artery atherosclerosis is common and is significantly correlated with both coronary and carotid disease (Sorensen *et al.*, 1997). Furthermore, there is a strong correlation between flow-mediated endothelium-dependent dilation in the coronary and brachial arteries. Thus, noninvasive assessment of flow-mediated dilation in the brachial artery may serve as a "surrogate" measure for coronary artery endothelial function (Takase *et al.*, 1998). The diameter of a conduit artery such as the brachial artery during an endothelium-dependent stimulus (e.g., shear stress created by reactive hyperemia) can be measured by high-resolution ultrasonography (Sorensen *et al.*, 1995). In patients with hypercholesterolemia or other risk factors for atherosclerosis, and in patients with coronary artery disease, this vasodilation is impaired (Celermajer *et al.*, 1992, 1994; Tawakol *et al.*, 1997).

Mechanisms of NO-Related Vascular Endothelial Dysfunction in Atherosclerosis and Hypercholesterolemia, and Associated Therapeutic Aspects

Several lines of evidence provide arguments that the mechanisms underlying the role of NO in vascular endothe-

lial dysfunction are diverse and likely multifactorial (Harrison, 1997). Indeed, the dysfunction may be situated at different levels of the L-arginine-NO pathway (Fig. 2): (1) dysfunctional receptor coupling and signal transduction, (2) decreased bioavailability of L-arginine, (3) altered expression and/or structure of endothelial NO synthase (eNOS), (4) altered eNOS activity, (5) increased destruction of NO, (6) changes in the balance of NO-endothelium-derived hyperpolarizing factor (EDHF), and (7) decreased sensitivity of atherosclerotic smooth muscle to NO. Each of these factors will be discussed in more detail.

DYSFUNCTIONAL RECEPTOR COUPLING AND SIGNAL TRANSDUCTION

A defect in membrane receptors or a defect in the signaling mechanisms activated by these receptors, for example, changes in the coupling and/or expression of G proteins, may account for a dysfunctional signal transduction of NO.

As described earlier endothelium-dependent relaxations in response to nonreceptor mediated stimuli such as the calcium ionophore A23187 are altered to a smaller extent as responses to receptor-mediated stimuli (Bossaller *et al.*, 1987). Therefore, there may be a defect in the membrane receptors and/or the signal transduction mechanism activated by these receptors as described later. However, this concept has been controversial because others have reported that the endothelium-dependent vascular relaxation to A23187 is also abnormal in vessels from hypercholesterolemic animals and humans (Förstermann *et al.*, 1988; Mügge *et al.*, 1991; Ohara *et al.*, 1993). The nature of the lesions (early or advanced) may account for these discrepancies (see later).

In the WHHL rabbit aorta progressive atherosclerosis differentially affects the activity of endothelial receptors: the most precociously altered is the P2y-purinoreceptor, followed by an impairment of the muscarinic and finally of the P2U-purinoreceptor (Ragazzi *et al.*, 1995).

A major mechanism for information transfer across the lipid bilayer of the cell border is the guanine nucleotide binding protein (G protein) signal transduction system. G proteins relay extracellular signals to activate or inhibit intracellular enzymes and ion channels. A number of distinct G proteins have been identified, including Gi protein, which inhibits adenylyl cyclase and activates K⁺ channels, Gs protein, which can activate adenylyl cyclase and calcium channels, and Gq protein, which activates phospholipase C. Certain G proteins can be ADP-ribosylated by pertussis toxin, resulting in an irreversible inhibition of their function. The endothelial pertussis toxin-sensitive G protein has been identified as a Gi protein, and couples certain endothelial receptors to the release of NO (e.g., muscarinic receptor, serotonin receptor, α_2 -receptor). Other endothelial receptors, including bradykinin and purinergic receptors, are coupled to the Gq protein, which is insensitive to pertussis toxin (Flavahan, 1992).

Alterations in G protein function represent another mechanism to explain the impaired endothelium-dependent vascular relaxation in hypercholesterolemia and after endothe-

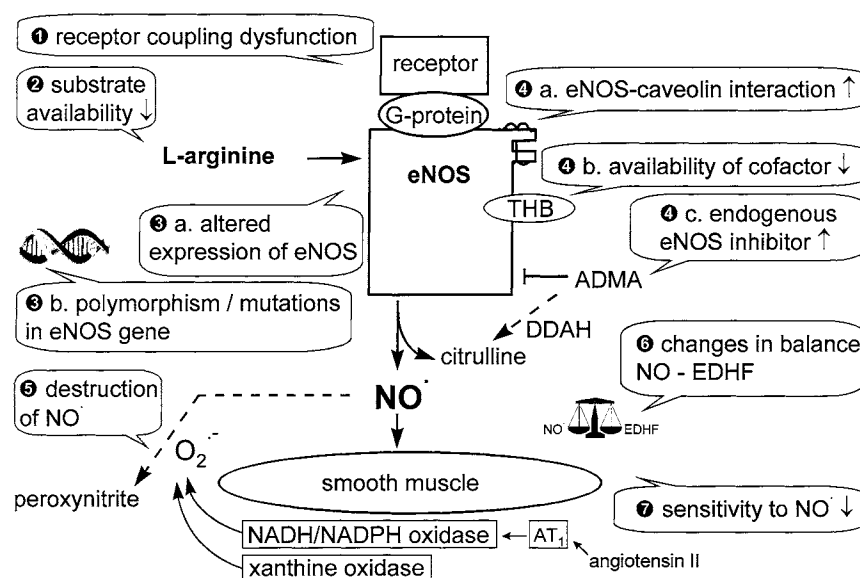

Figure 2 Mechanisms of NO-related vascular endothelial dysfunction in atherosclerosis and hypercholesterolemia. The mechanisms underlying the role of NO in vascular endothelial dysfunction are diverse and likely multifactorial. The dysfunction may be situated at different levels of the L-arginine–NO pathway: (1) dysfunctional receptor coupling and signal transduction, (2) decreased bioavailability of L-arginine, (3) altered expression and/or structure of endothelial NO synthase (eNOS), (4) altered eNOS activity, including enhanced inhibitory eNOS–caveolin interaction, decreased availability of tetrahydrobiopterin (THB), and elevated levels of an endogenous NO synthase inhibitor, (5) increased destruction of NO, (6) changes in the balance of NO to endothelium-derived hyperpolarizing factor (EDHF), and (7) decreased sensitivity of atherosclerotic smooth muscle to NO. For details, see text. ADMA, asymmetric dimethylarginine; DDAH, dimethylarginine dimethylaminohydrolase; AT₁, angiotensin II subtype 1 receptor.

lial regeneration (Bossaller *et al.*, 1987; Shimokawa *et al.*, 1990; Flavahan, 1992). Endothelial dysfunction appears to occur in distinct phases, and the underlying mechanisms may be determined by the stage of the disease or the concentration of oxidized LDL (oxLDL).

In the early stages of the atherosclerotic process or after low concentrations of oxLDL, the endothelial dysfunction appears to be limited to the pertussis toxin-sensitive Gi protein-dependent pathway. Indeed, responses to G protein-mediated agents, such as ACh, are abnormal, whereas responses to the calcium ionophore A23187, which bypasses G protein signaling, are relatively normal (Flavahan, 1992). Furthermore, endothelial exposure to atherogenic lipids, including lysophosphatidylcholine (lysoPC), is characterized by a selective impairment of responses mediated by the pertussis toxin-sensitive Gi protein (Freeman *et al.*, 1996).

The impairment of the interaction of the G proteins with the receptors that activates eNOS may be due to changes in membrane fluidity (Briggs and Lefkowitz, 1980). Other studies showed that the expression of Gi protein was inhibited by oxLDL *in vitro* (Liao and Clark, 1995) and in human coronary arteries by hypercholesterolemia, hypertension, and age (Tsutsui *et al.*, 1994). Furthermore, G proteins are anchored in the lipid bilayer by means of covalently linked apolar hydrocarbon chains and belong to the class of geranylgeranyl or farnesyl-anchored proteins. In cholesterol-fed rabbits exogenous cholesterol downregulates mevalonic acid

and subsequent farnesol biosynthesis. This may affect the G protein signal transduction pathway. Indeed, it has been shown that in hypercholesterolemic rabbits farnesol treatment restored impaired nitroergic [nonadrenergic, noncholinergic (NANC), neuronal NOS (nNOS)-mediated] relaxation of the sphincter of Oddi, presumably via a G protein related mechanism (Szilvassy *et al.*, 1998). Since the muscarinic receptor–eNOS signal transduction involves Gi proteins (Hare *et al.*, 1998; Flavahan, 1992) it is possible that farnesol also restores vascular endothelium-dependent relaxation via improvement of muscarinic receptor–eNOS signal transduction in endothelial cells of cholesterol-fed rabbits.

As atherosclerosis progresses or as the concentration of oxLDL is increased, dysfunction also occurs in endothelial mechanisms distinct from the Gi-protein-dependent pathway, such as a decrease in the bioavailability of L-arginine, a reduced sensitivity of the vascular smooth muscle cells to NO, or an increased breakdown of NO (cf. other mechanisms). This is illustrated by an impaired endothelium-dependent relaxations to A23187 (Flavahan, 1992).

DECREASED AVAILABILITY OF L-ARGININE

NO is formed from the amino acid L-arginine by NO synthase. In the blood the concentration of L-arginine is approximately 100 μ M (Böger *et al.*, 1997a). L-Arginine is actively transported into the endothelial cells by a cationic amino acid transporter, which colocalizes with eNOS in

caveolae (microdomains within the plasma membrane, *vide infra*) (McDonald *et al.*, 1997). The concentration of L-arginine in endothelial cells has been estimated to be several 100 μM (Hecker *et al.*, 1990), far above the K_m of NO synthase, which is about 5 μM (Harrison, 1997). Moreover, endothelial cells can resynthesize L-arginine from L-citrulline (Hecker *et al.*, 1990).

Although depletion of L-arginine is thus not likely to account for endothelial dysfunction, experiments in which exogenous L-arginine was given *in vitro* to vascular segments in organ chambers or *in vivo* to hypercholesterolemic animals and humans nevertheless produced contradictory results. The fact that extracellular L-arginine administration seems to drive NO production even when intracellular levels of L-arginine are available in excess, has been called the "arginine paradox" (Kurz and Harrison, 1997).

In *in vitro* studies L-arginine failed to correct the endothelial dysfunction of the aorta of cholesterol-fed (Bult *et al.*, 1990; Mügge and Harrison, 1991) and WHHL rabbits (Caparrotta *et al.*, 1993), as well as in human arteries (Cooper and Heagerty, 1998). Moreover, the intracellular concentration of L-arginine in endothelial cells can be varied over 100-fold without changing the production of NO (Arnal *et al.*, 1995).

In contrast, *in vivo* administration of L-arginine improved vascular responses to endothelium-dependent vasodilators, both in hypercholesterolemic animals and in humans (Kuo *et al.*, 1992; Girerd *et al.*, 1990; Cooke *et al.*, 1991; Drexler *et al.*, 1991), though the behavior of conduit arteries with atherosclerotic plaques was different from arterioles which do not develop atherosclerosis. In patients with hypercholesterolemia, L-arginine infusion improved or restored endothelium-dependent vasodilation in the coronary and peripheral arterioles without atherosclerosis (Drexler *et al.*, 1991; Creager *et al.*, 1992; Adams *et al.*, 1997). However, this was not confirmed by others (Casino *et al.*, 1994; Dakak *et al.*, 1998; Nitenberg *et al.*, 1998). In patients with coronary artery disease or peripheral artery occlusive disease L-arginine did not improve endothelium-dependent dilatation of conduit arteries with atherosclerotic plaques.

How can these contradictory and/or paradoxical effects of L-arginine be explained?

1. An explanation for why L-arginine is not effective in *in vitro* studies is the composition of the buffers used. L-arginine has no effect on endothelium-dependent vascular relaxations in a simple Krebs buffer. When L-glutamine is present in concentrations similar to those in the plasma, L-arginine enhances endothelium-dependent relaxations, possibly by reversing the inhibitory effect of L-glutamine in receptor-mediated NO release (Arnal *et al.*, 1995).

2. The levels of L-arginine in endothelial cells may be decreased due to induction of arginase and/or an increased arginase activity, which degrades L-arginine to ornithine and urea (Buga *et al.*, 1996). In normal endothelial cells arginase and not NO synthase is the major pathway of L-arginine metabolism (Wu and Meininger, 1995).

3. In endothelial cells the intracellular L-arginine may be sequestered in pools that are poorly accessible to eNOS. It has more recently been shown that the arginine transporter [cationic amino acid transporter 1 (CAT1)], eNOS, and caveolin (see later) colocalize in plasma membrane microdomains (caveolae). A caveolar complex between CAT1 and eNOS provides a mechanism for the directed delivery of extracellular L-arginine to membrane-bound eNOS and would account for the arginine paradox, that is, that extracellular L-arginine administration seems to drive NO production even when intracellular levels of L-arginine are available in excess (McDonald *et al.*, 1997). It also explains why caveolar localization of eNOS is required for optimal NO production by endothelial cells (see later).

4. Oral L-arginine supplementation inhibits the formation of intimal lesions in hypercholesterolemic rabbits (Cooke *et al.*, 1992; Wang *et al.*, 1994), reduces intimal hyperplasia after balloon injury in the rabbit, and improves endothelium-dependent vasorelaxation (McNamara *et al.*, 1993; Tarry and Makhoul, 1994). These effects of L-arginine have been proposed to be due to its metabolism to NO, as the effect is not mimicked by D-arginine. Moreover, L-arginine attenuates both platelet reactivity in hypercholesterolemic rabbits (Tsao *et al.*, 1994a) and the enhanced endothelial adhesiveness for monocytes (Tsao *et al.*, 1994b). In hypercholesterolemic rabbits dietary L-arginine also completely blocked the progression of plaques via restoration of NO synthase substrate availability, reduction of vascular oxidative stress (Böger *et al.*, 1997b), inhibition of cell proliferation, and vascular monocyte accumulation (Böger *et al.*, 1998). The endothelial dysfunction in the atherosclerotic rabbit aorta is dependent on the size of the plaque (Bult *et al.*, 1995). Therefore, it is likely that the antiatherogenic effect of L-arginine supplementation contributes to the improvement of endothelium-dependent relaxations. However, in arterioles of hypercholesterolemic rabbits (Girerd *et al.*, 1990) and pigs (Kuo *et al.*, 1992), which do not develop atherosclerotic plaques, endothelium-dependent vasodilation was slightly enhanced during L-arginine infusion. Therefore, L-arginine seems to exert additional effects.

5. Effects of L-arginine not related to its role as a substrate for NO synthase may account for the arginine paradox as well. L-arginine has a potent hormonal (i.e., insulin) secretagogue activity (Barbul, 1990; Giugliano *et al.*, 1997) which can influence vascular reactivity in general, as suggested by the similar shift of endothelium-independent relaxations after *in vivo* treatment with L-arginine (Cooke *et al.*, 1991).

6. In addition, in humans the nature of endothelial injury associated with individual cardiovascular risk factors might be different and this might affect the response to L-arginine. Although flow-mediated dilation is impaired in hypercholesterolemic subjects, smokers, and diabetic subjects, these three risk factor groups respond differently to L-arginine. Indeed, flow-mediated dilation is improved in hypercholesterolemic subjects and smokers but unchanged in diabetic subjects (Thorne *et al.*, 1998). Moreover, in healthy long-

term smokers acute administration of L-arginine reversed the abnormal myocardial blood flow response to cold pressor test. This test evokes a mixed, adrenergically mediated vasoconstrictor and vasorelaxant response; the vasorelaxant effects are thought to be mediated through β -adrenoceptor stimulation and through NO release from endothelial cells (Campisi *et al.*, 1999). Therefore, differing underlying pathophysiologies may facilitate the design of treatment strategies for subjects with different risk factors.

ALTERATIONS IN eNOS

Altered Expression of eNOS Although eNOS is constitutively present, its expression can be regulated. Exposure of cultured endothelial cells to tumor necrosis factor α (TNF- α), hypoxia, and high concentrations of oxLDL decreases the levels of eNOS (Liao *et al.*, 1995). It has been reported that the expression of eNOS is reduced in endothelial cells overlying advanced atherosclerotic plaques (Wilcox *et al.*, 1997). *In vitro* studies demonstrated that both eNOS mRNA and protein are downregulated by atherogenic concentrations of native LDL at a transcriptional level by a specific and concentration-dependent mechanism (Vidal *et al.*, 1998). In another study a marked reduction of immunoreactive eNOS in endothelial cells was accompanied by reduced NO release in atherosclerotic human carotid artery segments, as measured with a porphyrinic microsensor and compared to normal mammary arteries (Oemar *et al.*, 1998). Thus, in clinically relevant human atherosclerosis, eNOS protein expression and NO release are markedly reduced. In this way hypercholesterolemia induces early changes in endothelial cells that could have significance in the etiopathogenesis of the atherosclerotic process, including its progression. Also mechanical forces may downregulate eNOS levels in regions prone to the development of atherosclerosis (Ziegler *et al.*, 1998).

Although there is a loss of eNOS expression by endothelial cells covering advanced atherosclerotic lesions, there is a significant increase in overall NOS synthesis by other cell types in advanced lesions. The increased expression of NOS and presumably NO in atherosclerotic plaques may be related to cell death and necrosis in these tissues (Wilcox *et al.*, 1997). Also, explanted vein grafts with an intact endothelium demonstrate reduced focal expression of eNOS specific to atherosclerotic sites, which supports the view that vascular activity of NO is impaired in atherosclerosis. Reduced expression of eNOS may make an important contribution to this phenomenon (Buttery *et al.*, 1996). It has been shown that overexpression of eNOS with an adenoviral vector improves impaired NO-mediated relaxation in atherosclerotic arteries (Ooboshi *et al.*, 1998). Furthermore, although 3-hydroxy-3-methylglutaryl coenzyme A (HMG CoA) reductase inhibitors (statins) restore endothelial function by reducing serum cholesterol levels, they can also directly upregulate eNOS expression. Atorvastatin and simvastatin prevent the inhibitory action exerted by oxLDL on eNOS mRNA and protein levels. The effects on eNOS expression correlate with changes in eNOS activity. Thus,

HMG CoA reductase inhibitors may have beneficial effects in atherosclerosis beyond that attributed to the lowering of serum cholesterol by increasing eNOS activity (Laufs *et al.*, 1998; Hernandez-Perera *et al.*, 1998).

In contrast, WHHL rabbit aortas show significantly impaired endothelium-dependent relaxations, although *in situ* hybridization and immunohistochemistry, respectively, exhibit enhanced expression of eNOS mRNA and protein in WHHL aortas (Kanazawa *et al.*, 1996). Similarly, low concentrations of oxLDL and lysophosphatidylcholine upregulate eNOS mRNA in bovine aortic endothelial cells (Hirata *et al.*, 1995).

Polymorphism/Mutations in the eNOS Gene A common polymorphism in exon 7 of the eNOS gene (894G \rightarrow T) has been reported to be a strong risk factor for coronary artery disease. Markus *et al.* (1998) failed to find a relationship between this exon 7 polymorphism and ischemic cerebrovascular disease. In particular, it was not associated with stroke and transient ischemic attack secondary to large-vessel atherosclerosis or with the degree of carotid stenosis in patients with cerebrovascular disease. However, the missense Glu298Asp variant in exon 7 of the eNOS gene is significantly associated with myocardial infarction (Shimasaki *et al.*, 1998; Hibi *et al.*, 1998), essential hypertension (Miyamoto *et al.*, 1998), and coronary spasm (Yoshimura *et al.*, 1998). This marker-disease association may be due to the impaired effects of NO on the cardiovascular system, such as dysregulation of vascular tone, platelet aggregation and leukocyte adhesion, and smooth muscle cell proliferation. Furthermore, it has more recently been shown that the T⁻⁷⁸⁶ \rightarrow C mutation in the 5'-flanking region of the eNOS gene is associated with coronary spasm and results in a significant reduction in eNOS gene promoter activity (Nakayama *et al.*, 1999).

ALTERATIONS IN eNOS ACTIVITY

Alterations of eNOS activity can be due to several factors, such as: (a) enhanced inhibitory eNOS-caveolin interaction (Fig. 3); (b) decreased availability of tetrahydrobiopterin; and (c) elevated levels of an endogenous NO synthase inhibitor.

Enhanced Inhibitory eNOS-Caveolin Interaction NO production in the vascular endothelium is promoted by diverse agonists that transiently increase intracellular Ca^{2+} concentration and activate eNOS, a Ca^{2+} /calmodulin-dependent enzyme. eNOS is acylated by the fatty acids myristate and palmitate and is targeted thereby to plasmalemmal signal-transducing domains termed caveolae. Caveolae are small invaginations in the plasma membrane characterized by the presence of the transmembrane protein caveolin. eNOS enzyme activity is markedly attenuated by its interactions with caveolin, the structural scaffolding protein of caveolae. In living cells, the eNOS-caveolin heteromeric complex undergoes cycles of dissociation and reassociation

Figure 3 eNOS–caveolin interaction. Caveolae are small invaginations in the plasma membrane characterized by the presence of the transmembrane protein caveolin. The interaction of eNOS with caveolin maintains the enzyme in its inactivated state. The calcium regulatory protein calmodulin, which is enriched in the caveolar fraction of plasma membranes, does not bind to eNOS in the absence of Ca^{2+} . After agonist activation or other stimuli causing a local increase in the intracellular Ca^{2+} concentration, Ca^{2+} -bound calmodulin competitively displaces caveolin from eNOS. This allows the conformational changes within eNOS required for electron transfer, leading to the synthesis of NO by the activated enzyme. Exposure of endothelial cells to the serum of hypercholesterolemic individuals or its LDL fraction upregulates caveolin abundance, without a change in eNOS protein levels. This is associated with increased inhibitory eNOS–caveolin complex formation, accompanied by an impairment of NO production. (After Michel and Feron, 1997, and Feron *et al.*, 1999.)

modulated by Ca^{2+} -mobilizing agonists. Calcium ionophore A23187 and the muscarinic cholinergic agonist carbamylcholine both promote the dissociation of eNOS from caveolin in cultured cells, associated with translocation of eNOS from caveolae. Thus, after agonist activation, the increase in $[Ca^{2+}]_i$ promotes calmodulin binding to eNOS and the dissociation of caveolin from eNOS. As $[Ca^{2+}]_i$ returns to basal levels, eNOS reassociates with caveolin, and the inhibited enzyme complex is then restored to caveolae, a process accelerated by palmitoylation of the enzyme. Taken together, in the eNOS–caveolin regulatory cycle eNOS activation is modulated by reversible protein–protein interactions controlled by Ca^{2+} /calmodulin and by enzyme palmitoylation (Michel and Feron, 1997).

More recently, it has been shown that exposure of endothelial cells to the serum of hypercholesterolemic individuals or its LDL fraction upregulates caveolin abundance, without a change in eNOS protein levels. This is associated with increased inhibitory eNOS–caveolin complex formation, accompanied by an impairment of both basal and calcium ionophore A23187-stimulated NO production (Feron *et al.*, 1999). The findings with A23187, a receptor-independent agonist for eNOS stimulation, exclude the G protein-coupled receptor signaling cascade in this effect. Since this impairment in NO release by endothelial cells occurs in the

absence of any change in eNOS protein levels it may be one of the early events among the proatherogenic processes induced by hypercholesterolemia. Indeed, the early impairment of NO-mediated vascular relaxation in hypercholesterolemia is generally observed without a decrease in eNOS protein level (Kanazawa *et al.*, 1996) or angiographically or ultrasound-detectable changes of the vessel wall (Seiler *et al.*, 1993; Reddy *et al.*, 1994). Thus, in early atherogenesis eNOS activity appears to be regulated at the posttranslational level (Feron *et al.*, 1999). Furthermore, because it has been shown that an increase in shear stress is associated with an increase in NO production rate and eNOS phosphorylation, also the degree of phosphorylation of eNOS may play a role in NO-related vascular endothelial dysfunction (Corson *et al.*, 1996).

Decreased Availability of Tetrahydrobiopterin Tetrahydrobiopterin is an essential cofactor required for catalytic activity of NO synthases. The precise role of tetrahydrobiopterin in regulation of NO synthase activity is not completely understood. It may function as both an allosteric and redox cofactor. It appears to contribute to the binding of L-arginine to NO synthase (Harrison, 1997) and has antioxidative activity (Kojima *et al.*, 1995). In peripheral and cerebral arteries, administration of tetrahydrobiopterin can stimulate the pro-

duction of NO. In contrast, in arteries depleted of tetrahydrobiopterin, NO production is impaired. In the absence of tetrahydrobiopterin NO synthase transfers an electron to oxygen. Consequently, superoxide anion is formed (Pou *et al.*, 1992). Decreased availability of tetrahydrobiopterin may be responsible for a dysfunction of NO synthase leading to a shift in the balance between the production of protective NO and deleterious oxygen-derived free radicals (Cosentino and Lüscher, 1998). It has been demonstrated that tetrahydrobiopterin (or a derivative) restores endothelial function in aortic rings from diabetic rats *in vitro* (Pieper, 1997) and in hypercholesterolemic patients (forearm blood flow) (Stroes *et al.*, 1997). This effect may be explained by an increased production of NO and/or by the antioxidative capacity of tetrahydrobiopterin.

Elevated Levels of an Endogenous NO Synthase Inhibitor A circulating endogenous NO synthase inhibitor, asymmetric dimethylarginine (ADMA), has been detected in human plasma (Fickling *et al.*, 1993; Pettersson *et al.*, 1997). High levels of ADMA have been shown in the plasma of cholesterol-fed rabbits (Bode-Böger *et al.*, 1996), in the regenerating endothelium of balloon injured vessels (Azuma *et al.*, 1995), in the urine of hypertensive rats (Matsuoka *et al.*, 1997), and in patients with peripheral arterial occlusive disease (Böger *et al.*, 1997a). However, the intracellular levels of these endogenous antagonist in different cardiovascular diseases are not known. Plasma dimethylarginines arise mainly from degradation of intracellular methylated proteins and are eliminated via urinary excretion (McDermott, 1976). ADMA is metabolized to citrulline by dimethylarginine dimethylaminohydrolase (DDAH) (Ogawa *et al.*, 1989). Inhibitors of DDAH block ADMA degradation and induce a contraction of isolated vascular rings (MacAllister *et al.*, 1996), which is consistent with the concept that ADMA produced by vascular cells modulates the synthesis of NO by the endothelial cells. Taken together, plasma and/or vascular ADMA may be increased due to an increased degradation of methylated proteins, a decreased renal filtration, and/or a decreased activity of DDAH.

In vivo, L-arginine supplementation may overcome the competitive inhibition evoked by ADMA, which offers a possible explication for the restoration of endothelial NO-mediated vasodilation (Cooke and Dzau, 1997). In addition, a more recent study reveals that plasma ADMA levels are positively correlated with risk factors for atherosclerosis (mean arterial blood pressure, incremental area of plasma glucose level over time, and age) and that plasma ADMA levels are significantly correlated with intima-media thickness of the human carotid artery (Miyazaki *et al.*, 1999).

OVERPRODUCTION OF OXYGEN-DERIVED FREE RADICALS AND DESTRUCTION OF NO

Several studies in animals and humans provide arguments that oxidative inactivation of NO may also be important as an explanation for vascular endothelial dysfunction. The endothelium generates superoxide anions under basal condi-

tions and may be stimulated to generate excess superoxide anions by several factors. Indeed, infusion of the antioxidant ascorbic acid (vitamin C) improves vascular responses to ACh or metacholine in cigarette smokers, in diabetics, in patients with hypertension, in chronic heart failure, and in patients with hypercholesterolemia (Heitzer *et al.*, 1996; Ting *et al.*, 1996, 1997; Solzbach *et al.*, 1997; Hornig *et al.*, 1998a), which supports the notion that these conditions are associated with increased radical formation that in turn affects endothelium-mediated vasomotor tone.

Thus, in arteries subject to hypercholesterolemia or atherosclerosis the biological activity of NO is attenuated, whereas its synthesis might be normal. This may be caused by its inactivation in the intima by components of oxidized lipoproteins acting directly (by reaction with NO), indirectly (by stimulation of release of NO scavengers), or both. Thus, in hypercholesterolemia the normal balance between NO availability and lipoprotein oxidation is shifted to favor a self-reinforcing cycle of NO depletion and accelerated lipoprotein oxidation that may ultimately lead to atherosclerosis (Jessup, 1996).

In a randomized double-blind placebo-controlled study of patients with angiographically proven coronary artery disease, the augmentation of cellular glutathione levels by L-2-oxo-4-thiazolidine carboxylate improved endothelium-derived NO action, as assessed by brachial artery flow-mediated dilation. Therefore, cellular redox state may be an important regulator of endothelium-derived NO action, and is a potential target for therapy in patients with coronary artery disease (Vita *et al.*, 1998).

In cholesterol-fed rabbits, the aortic endothelial cells produce excess quantities of nitrogen oxides with minimal vasodilator activity (Minor *et al.*, 1990), which suggests that NO is inactivated before being released from the endothelial cell. In this model chronic treatment with polyethylene glycolated superoxide dismutase partially restores endothelium-dependent vascular relaxations (Mügge *et al.*, 1991), which favors the concept that an increased superoxide anion production in hypercholesterolemia destroys endothelium-derived NO. Vascular superoxide anion production in this model is inhibited by oxypurinol (White *et al.*, 1996). Therefore, superoxide anion seems to be formed by xanthine oxidase. In the plasma of cholesterol-fed rabbits this enzyme is increased. Circulating xanthine oxidase has been shown to bind to heparin-binding sites on the vessel, where it produces superoxide anions (White *et al.*, 1996). Also the results of Warnholtz *et al.* (1999) are suggestive that vascular and/or circulating xanthine oxidase is a significant source of superoxide anion in hypercholesterolemic rabbits. An additional flavin-containing oxidase, such as NADH/NADPH oxidase, probably serves as a source of superoxide anion in hypercholesterolemic vessels (Warnholtz *et al.*, 1999). NADH/NADPH oxidase has been demonstrated to be the predominant superoxide source in both endothelial and smooth muscle cells (Mohazzab-H. *et al.*, 1994; Griendling *et al.*, 1994). In homogenates of aortas from WHHL rabbits and cholesterol-fed rabbits NADH oxidase activity was increased as com-

pared to controls (Warnholtz *et al.*, 1999). It has been shown that the activity of NADH/NADPH oxidase is regulated by angiotensin II. Activation of the angiotensin II subtype 1 (AT₁) receptor increases the activity of (membrane-associated) NADH/NADPH oxidase in smooth muscle cells (Griendling *et al.*, 1994) and endothelial cells (Lang *et al.*, 1997). In atherosclerotic lesions the expression of angiotensin converting enzyme (ACE) is increased (Diet *et al.*, 1996). Moreover, hypercholesterolemia is associated with enhanced expression of the AT₁ receptor (Nickenig *et al.*, 1997).

Endothelial dysfunction in hypercholesterolemic animals and in humans is improved by ACE-inhibitors. The TREND (trial on reversing endothelial dysfunction) trial showed that ACE inhibition with quinapril improved endothelial dysfunction in patients with coronary artery disease who were normotensive and who did not have severe hyperlipidemia or evidence of heart failure (Mancini *et al.*, 1996). How can this beneficial effect be explained in relation to the L-arginine–NO pathway? ACE inhibition inhibits the breakdown of bradykinin. It is of interest that endothelial cells can produce and release bradykinin locally, particularly in response to flow and shear stress. Locally released bradykinin may then activate B2-bradykinin receptors on endothelial cells and activate the endothelial L-arginine–NO pathway (Büsse and Lamontagne, 1991), as well as EDHF (Holzmann *et al.*, 1994). A bradykinin antagonist partly diminishes this effect. Therefore, the protective effect of ACE inhibitors has been attributed to inhibition of bradykinin breakdown, with subsequent high concentrations of NO and EDHF, rather than inhibition of angiotensin formation itself. However, improvement in endothelium-dependent vasodilation and vascular superoxide anion production can be achieved independently of bradykinin preservation. AT₁-receptor blockade inhibits NADH-oxidase activity and in parallel improves endothelial dysfunction in cholesterol-fed rabbits (Warnholtz *et al.*, 1999). Thus, the increased activity of NADH oxidase in hypercholesterolemia may be due to increased local angiotensin II generation and may be partly responsible for the enhanced superoxide production. Therefore, angiotensin II may play a crucial role in superoxide anion production and endothelial dysfunction in the early stage of atherosclerosis. Taken together, the renin–angiotensin system and the L-arginine–NO pathway are interconnected. Modulation of NO generation and degradation by, respectively, bradykinin and superoxide anions contribute to the beneficial effect of ACE inhibitors when the endothelium is dysfunctional.

CHANGES IN THE BALANCE OF NO-EDHF

In some blood vessels, such as the rabbit carotid and porcine coronary arteries, inhibition of eNOS only slightly attenuates endothelium-dependent relaxations. These relaxations are mediated by an endothelial factor distinct from NO, which has been named endothelium-derived hyperpolarizing factor (EDHF) since it hyperpolarizes the vascular smooth muscle cells, most likely by opening calcium-sensitive potassium channels. The chemical nature of EDHF is still unclear. There is evidence that in coronary, cerebral, and

renal arteries EDHF is a cytochrome P-450 monooxygenase-derived arachidonic acid metabolite, an epoxyeicosatrienoic acid. The rabbit carotid artery and rabbit aorta have EDHF activity but do not produce metabolites of arachidonic acid by the cytochrome P-450 pathway. Thus, some other compound(s), possibly NO or another metabolite of arachidonic acid, may mediate the effect (Campbell and Harder, 1999). In isolated arteries proinflammatory mediators inhibit the formation of EDHF. This impairment is coincident with inducible NOS (iNOS) expression in the arterial wall and seems to be mediated through the induced generation of NO, which downregulates the EDHF-forming enzyme. Thus, a decreased formation of EDHF may contribute to the endothelial dysfunction in atherosclerosis (Kessler *et al.*, 1999). The contribution of EDHF to endothelium-dependent relaxations is significantly larger in microvessels than in large arteries. Aging and hypercholesterolemia significantly impair EDHF-mediated relaxations (Urakami-Harasawa *et al.*, 1997).

In the renal artery from hypercholesterolemic rabbits the nitro-L-arginine-resistant part of ACh-induced endothelium-dependent relaxation was enhanced, in comparison to arteries from normal animals. Possibly, differences in the balance between NO- and EDHF-mediated control of vascular tone may maintain ACh-induced vasodilation (Brandes *et al.*, 1997).

DECREASED SENSITIVITY OF ATHEROSCLEROTIC SMOOTH MUSCLE TO NO

In contrast to endothelium-dependent agonists, the relaxations in response to the endothelium-dependent exogenous NO donors NTG or sodium nitrate are normal or near normal in atherosclerotic blood vessels (Bossaller *et al.*, 1987; Freeman *et al.*, 1986; Jayakody *et al.*, 1987; Verbeuren *et al.*, 1986). The vasodilator actions of exogenous nitrovasodilators may even be augmented acutely by endothelial removal and chronically by diseases that damage the endothelial lining. Basal formation of NO may interfere with the relaxant effects to exogenous nitrovasodilators. The removal of this basal influence of NO seems to sensitize the guanylyl cyclase to agents that act by the stimulation of this pathway (Guerra *et al.*, 1989). However, as atherosclerosis progresses it may also interfere more directly with vascular smooth muscle cell relaxation. In rabbit aortae with severe fatty streak formation the relaxations induced by NTG are reduced (Verbeuren *et al.*, 1990). Moreover, the endothelium-independent relaxations evoked by atrial natriuretic factor are attenuated in thoracic aortae from hypercholesterolemic rabbits (Verbeuren *et al.*, 1990). Also the relaxations evoked by ATP are inhibited more in the atherosclerotic rabbit aortic arch than in a control aortic arch without endothelium (Verbeuren *et al.*, 1986). In addition, vessels with severe atherosclerosis taken from WHHL rabbits are less sensitive to NTG (Kolodgie *et al.*, 1990). Moreover, it has been shown that there is a substantial resistance to NO action in aortic smooth muscle cells of cholesterol-fed rabbits. This is consistent with the notion that resistance of smooth muscle cells to NO contributes to

abnormal endothelium-dependent vasodilation during hypercholesterolemia and can play a role in the pathogenesis of atherosclerosis (Weisbrod *et al.*, 1997). Moreover, the vasodilator response to exogenous NO is impaired in asymptomatic subjects with reduced endothelium-dependent dilation, consistent with smooth muscle dysfunction in adults at risk for atherosclerosis (Adams *et al.*, 1998). Taken together, these findings indicate that smooth muscle cell responsiveness to vasodilator substances is affected as atherosclerosis progresses.

Endothelium-Mediated Relaxation after Balloon Catheter De-endothelialization and Balloon Angioplasty

The mechanism of dilation by balloon angioplasty is disruption or splitting of the plaque and stretching of the underlying arterial wall to increase the intraluminal diameter of the vessel. Although the removed endothelium may regrow from the edges of the lesion, its function may not return to normal. The degree and duration of endothelial dysfunction seem to depend on the severity of the initial injury and also seem to be related to the extent of intimal thickness. The endothelium-dependent relaxation of balloon-injured vessels to ACh and to the calcium ionophore A23187 was reduced at 2 and at 4 weeks after severe injury (Weidinger *et al.*, 1990). Bosmans *et al.* (1996) demonstrated that although regeneration of endothelial cells was complete within 2 weeks, the endothelium-dependent relaxations evoked by ACh remained impaired even up to 10 weeks after dilation. Thus, although the endothelium quickly regenerated after severe balloon injury, the endothelium-dependent release of NO remained disturbed. However, angioplasty also led to a significant induction of NOS in "nonendothelial" cells of the artery (Bosmans *et al.*, 1996).

After moderate injury, endothelium-dependent relaxations to ACh and A23187 were reduced at 2 weeks but had normalized by 4 weeks (Weidinger *et al.*, 1990). Dysfunction of a pertussis toxin-sensitive G protein partly accounted for the endothelial abnormality in the chronic regenerated state (Shimokawa *et al.*, 1990).

Implications of Endothelial Dysfunction in Atherosclerosis

It is becoming clear that NO, in addition to regulating vasomotion, might also modulate the progression of atherosclerosis, and the restenosis process after balloon angioplasty (Bult, 1996). NO appears to inhibit atherogenesis by inhibiting leukocyte adhesion and platelet adhesion and aggregation and by inhibiting smooth muscle cell proliferation and migration. Since the renin-angiotensin system and the L-arginine-NO pathway are interconnected (see earlier) modulation of NO generation and degradation, respectively, by bradykinin and superoxide anions contribute to the beneficial effect of ACE inhibitors in atherogenesis.

Excess of LDL cholesterol leads to selective impairment of NO-dependent vasodilation (forearm blood flow measured by venous occlusion plethysmography) even in young adults, whereas adenylyl cyclase-dependent vasodilation of vascular smooth muscle and maximal dilatory capacity are preserved. In view of the antiatherogenic properties of NO, it appears desirable to detect this selective vascular dysfunction early in young adults at high risk of developing atherosclerotic lesions (Preik *et al.*, 1996a).

However, like the Roman god Janus, NO seems to have a double face in the atherogenic process. In atherosclerosis, diabetes mellitus, and high renin hypertension, there is increased production of superoxide. Superoxide rapidly reacts with NO to form the highly reactive intermediate peroxynitrite (ONOO⁻). Peroxynitrite reacts relatively slowly with most biological molecules, making peroxynitrite a selective oxidant. Peroxynitrite modifies tyrosine in proteins to create nitrotyrosines, leaving a footprint detectable *in vivo*. Antibodies to nitrotyrosine have revealed nitration in several diseases, including human atherosclerosis and myocardial ischemia (Beckman and Koppenol, 1996). Peroxynitrite can be protonated to form peroxynitrous acid which in turn can yield the hydroxyl radical (OH[•]). These reactive species can oxidize lipids, damage cell membranes, and oxidize thiol groups. NO given locally, exerts potent antiatherosclerotic effects such as inhibition of platelet aggregation, inhibition of adhesion of leukocytes, and the expression of leukocyte adhesion molecules. However, *in vivo* treatment with NO (via organic nitrates) increases rather than decreases oxidant load within endothelial cells. It remains therefore questionable whether systemic treatment with NO may have antiatherosclerotic properties or whether NO may initiate or even accelerate the atherosclerotic process (Münzel *et al.*, 1997; Bult, 1996; Leeuwenburgh *et al.*, 1997).

Manipulation of the L-arginine-NO-cGMP pathway may provide novel therapeutic approaches for limiting atherogenesis and neointimal proliferation in the future. For example, estrogens have atheroprotective properties, the mechanisms of which are not completely understood. Some of the benefits of estrogens can be ascribed to their ability to favorably alter the lipoprotein profile, that is, increase in high density lipoprotein and decrease in low density lipoprotein. In addition, estrogens have been reported to augment eNOS activity without altering gene expression, which was accompanied by a rapid increase in basal NO release (Caulin-Glaser *et al.*, 1997) (see also later). This effect may be, at least in part, mediated by a novel action of the estrogen receptor α (Chen *et al.*, 1999). Ethinylestradiol also prevents the degradation of NO by decreasing superoxide anion production (Arnal *et al.*, 1996). Increased NO bioavailability would promote vasodilation. Indeed, physiological concentrations of 17 β -estradiol selectively enhance endothelium-dependent coronary vasodilation in postmenopausal women, an effect that was mediated by enhanced bioavailability of NO (Guetta *et al.*, 1997). In addition, increased NO bioavailability can inhibit proliferation of vascular smooth muscle cells, reduce platelet aggregation, and inhibit monocyte

adhesion to the endothelium and the inflammatory reaction induced by cytokines, all key contributors in the development of atherosclerosis. However, it has also been shown that prevention of fatty streak formation by 17β -estradiol is not mediated by the production of NO in apolipoprotein E-deficient mice (Elhage *et al.*, 1997).

Endothelial Dysfunction in Hypertension

Impaired release of NO occurs in most animal and human models of hypertension, contributing to the increased peripheral resistance and most likely to the development of cardiovascular complications. Many *in vitro* studies have reported endothelial dysfunction in thoracic aortae of spontaneously hypertensive rats (SHR) (Konishi and Su, 1983; Lüscher and Vanhoutte, 1986; Carvalho *et al.*, 1987; Shirasaki *et al.*, 1988), in the New Zealand hypertensive rat (Winkvist *et al.*, 1984), in the deoxycorticosterone–salt model, the one-kidney, one-clip model (Van De Voorde and Leusen, 1986), and in aortic coarctation (Lockette *et al.*, 1986). Also, in patients with essential hypertension endothelium-dependent relaxation is diminished (Linder *et al.*, 1990; Panza *et al.*, 1990).

Endothelial dysfunction is largely due to reduced bioactivity of NO (Panza *et al.*, 1993a) and is not related to decreased availability of L-arginine (Panza *et al.*, 1993b). Moreover, it is not isolated to a specific defect of one endothelial cell surface receptor (Panza *et al.*, 1994). In patients with essential hypertension, endothelium-dependent vasodilation to ACh and bradykinin is impaired. These findings indicate that the endothelial dysfunction in this condition is not related to a specific defect of a single intracellular signal-transduction pathway and suggest a more generalized abnormality of endothelial vasodilator function (Panza *et al.*, 1995). Thus, these results contrast with those obtained in hypercholesterolemic patients in whom the response to ACh is impaired but the response to bradykinin is preserved (see earlier). In conjunction, these observations suggest that an NO defect of the hypertensive vasculature may lie distal to the G protein step in endothelial cell signal transduction. A reduced soluble guanylyl cyclase expression appears to contribute to vasodilator dysfunction in SHR (Bauersachs *et al.*, 1998). Moreover, in the endothelial dysfunction observed in hypertension, angiotensin II-stimulated NADH/NADPH oxidase activity and subsequent superoxide anion production plays a role as well. Indeed, in rats made hypertensive by infusions of angiotensin II, endothelium-dependent vascular relaxations are impaired. The vessels show an increased NADH/NADPH oxidase activity and produce increased amounts of superoxide (Rajagopalan *et al.*, 1996). Furthermore, in essential hypertensive patients, impaired endothelial vasodilation can be improved by the antioxidant vitamin C, as shown by forearm blood flow measurements. This effect can be reversed by the NO synthase inhibitor N^G -monomethyl-L-arginine (Taddei *et al.*, 1998). Therefore, NO inactivation by oxygen free radicals seems to contribute to endothelial dysfunction in essential hypertension. In contrast

to hypercholesterolemic patients, the xanthine oxidase system does not appear to play a significant role in the impaired endothelial vasodilator function in essential hypertension (Cardillo *et al.*, 1997).

In contrast to essential hypertension, preeclampsia, which is a hypertensive disorder unique to human pregnancy, selectively impairs endothelium-dependent relaxation: responses to bradykinin are similar in vessels from normal pregnant and preeclamptic women whereas those to ACh are absent in vessels from women with preeclampsia (Pascoal *et al.*, 1998).

Another mechanism to explain reduced agonist-induced endothelium-dependent relaxations in essential hypertension is a concomitant release of vasoconstrictor prostanoids (endoperoxides and thromboxane A₂), which is associated with aging. These prostanoids may be produced in the vascular smooth muscle rather than in the endothelium (Shimokawa, 1998). Enhanced production of an endothelial contractile factor is apparently not involved in the depressed endothelium-dependent responses of aortae from renal hypertensive rats (Van De Voorde and Leusen, 1986). In these vessels endothelium-dependent hyperpolarization is largely depressed; this might contribute to the impaired endothelium-dependent relaxation in hypertension (Van De Voorde *et al.*, 1992).

Endothelial dysfunction appears to occur in large but not small arteries in human and animal hypertension. Indeed, in contrast with the findings in isolated conduit arteries, endothelium-dependent relaxation is unimpaired in mesenteries from transgenic hypertensive rats. However, there are differences in the relative contributions of NO and EDHF, such that inhibition of either NO or EDHF alone in mesenteries from transgenic hypertensive rats has less impact as compared to mesenteries from normotensive controls. The relationship between NO and EDHF has more recently been shown to be dynamic, with EDHF activity becoming upregulated on loss of basal or coreleased NO due to a cGMP-mediated modulation at the smooth muscle cells (McCulloch *et al.*, 1997). Thus, this reciprocal relationship between NO and EDHF may be upregulated in the mesenteries from transgenic hypertensive rats. EDHF may be more effective at compensating for the loss of NO in the transgenic hypertensive rats (Randall and March, 1998).

ACE inhibitors prevent the impairment of NO-mediated vasodilation in experimental hypertension in animals. Because this endothelial protective effect can be obtained with different ACE inhibitors, it is likely to be a drug class effect. Moreover, in SHR endothelial dysfunction and subendothelial monocyte macrophage infiltration are associated (Clozel *et al.*, 1991). There is an association between improvement of endothelial function and decrease of monocyte macrophage infiltration shortly after short-term treatment with the ACE inhibitor cilazapril (Clozel *et al.*, 1991). The improvement in endothelial function by cilazapril might be responsible for the decrease in monocyte macrophage infiltration because quiescent endothelial cells inhibit leukocyte adherence and chemotactic activity (Zimmermann *et al.*, 1985). In

contrast to animal models, the ACE inhibitors captopril and enalapril were unable to improve or even normalize impaired endothelium-dependent vasodilation in hypertensive patients (Creager and Roddy, 1994). This lack of effect may be related to (1) the duration of therapy, (2) the start of the treatment in relation to the stage of hypertension (in animal models treatment is usually started before hypertension develops), (3) the lipophilicity and tissue selectivity of the ACE inhibitors used, and (4) the processing of angiotensin I to angiotensin II by other enzymes (Ruschitzka *et al.*, 1998). In NO-deficient hypertensive rats, long-term but not short-term therapy with the calcium antagonist verapamil improves impaired endothelium-dependent relaxations (Takase *et al.*, 1996). In SHR, chronic therapy with the calcium channel blocker nifedipine or isradipine ameliorates impaired endothelium-dependent relaxations to ACh (Tschudi *et al.*, 1994).

In hypertensive patients dilation of resistance arteries in response to infusion of NO donors is impaired, and the degree of this impairment depends critically on the severity of arterial hypertension. The reduced effectiveness of NO appears to be independent of the class of NO donor and thus of the mode of intravascular NO generation (Preik *et al.*, 1996b).

Endothelial Dysfunction in Diabetes

Observations in Animals and Humans

Diabetes mellitus is associated with early development of cardiovascular complications. Evidence for endothelial dysfunction in diabetes comes from studies that measured endothelial substances that mediate fibrinolysis and coagulation. In both type I and type II diabetes, fibrinolytic activity is decreased and plasminogen activator inhibitor activity increased (Auwerx *et al.*, 1988). Moreover, von Willebrand factor, which is synthesized within endothelial cells and may be a marker of endothelial damage, circulates in increased concentrations in diabetics (Bensoussan *et al.*, 1975). There is also substantial evidence that endothelium-dependent vasodilation is abnormal in both conduit arteries and resistance vessels of diabetic animals (Meraji *et al.*, 1987; Durante *et al.*, 1988; Mayhan, 1989; Tesfamariam *et al.*, 1989; Abiru *et al.*, 1990; Lash and Bohlen, 1991). However, not all studies have confirmed abnormal endothelium-dependent vasodilation in diabetic animals (Fortes *et al.*, 1983; Harris and MacLeod, 1988). The reasons for the discrepancies may be related to the duration of diabetes, species, gender, the inducer of diabetes, or the choice of the artery (Johnstone *et al.*, 1993). Also endothelium-dependent hyperpolarization is reduced by diabetes, and this would, in part, account for the impaired endothelium-dependent relaxations in mesenteric arteries from diabetic rats (Fukao *et al.*, 1997).

In patients with insulin-dependent diabetes mellitus (IDDM) endothelium-dependent vasodilation is abnormal in forearm resistance vessels (Johnstone *et al.*, 1993). Calver *et al.* (1992) reported impaired basal release of NO in these

vessels. In patients with noninsulin-dependent diabetes mellitus (NIDDM) the dilator responses to both ACh and NTG are reduced (McVeigh *et al.*, 1992), but endothelium-derived basal NO formation is not impaired (Catalano *et al.*, 1997). However, in these individuals the ability of the vascular smooth muscle cells to respond to vasodilator stimuli may be disturbed, because these patients are generally older than insulin-dependent diabetics and are often affected by hypertension and hyperlipidemia (Johnstone *et al.*, 1993).

Decreased NO activity in diabetes can be caused by (1) deficiency of the NOS substrate L-arginine, (2) abnormalities in signal transduction due to decreased expression of inhibitory G proteins, reduced phosphoinositol metabolism, and increased activation of protein kinase C (Gawler *et al.*, 1987; Greene *et al.*, 1987; Lee *et al.*, 1989), (3) a decreased availability of one or more cofactors essential for optimal functioning of NOS, (4) generation and release of vasoconstrictor prostanoids that counteract the effect of NO (Mayhan, 1989; Tesfamariam *et al.*, 1989), and (5) accelerated inactivation of NO due to high levels of oxygen-derived free radicals, advanced glycosylation end products (AGEs, see later), and transport barriers such as thickened basement membranes (Pieper and Gross, 1988; Tesfamariam, 1994; Bucala *et al.*, 1991; Siperstein *et al.*, 1968). We will discuss some of these possibilities in more detail.

Mechanisms of NO-Related Vascular Endothelial Dysfunction

BIOAVAILABILITY OF L-ARGININE

In diabetic rats the concentration of L-arginine in plasma and aortic tissue are both decreased. In aortic rings from diabetic rats acute L-arginine supplementation *in vitro* restores endothelium-dependent relaxation by augmenting cGMP production (Pieper and Dondlinger, 1997; Pieper *et al.*, 1997a). Similarly, acute dietary supplementation with L-arginine *in vivo* in diabetic rats reverses the defective endothelium-dependent relaxation in diabetic blood vessels assessed *ex vivo* (Pieper *et al.*, 1996a). In contrast, as already discussed above, flow-mediated dilation in humans is impaired in hypercholesterolemic subjects, smokers, and diabetic subjects. These three risk factor groups responded differently to L-arginine. Flow-mediated dilation is improved in hypercholesterolemic subjects and smokers but unchanged in diabetic subjects (Thorne *et al.*, 1998). This discrepancy may be related to the stage of diabetes. Indeed, in experimental diabetes a defect in substrate/supply for NO synthesis is acutely reversed by L-arginine supplementation at early but not at later stages of diabetes (Pieper *et al.*, 1996b).

SIGNAL TRANSDUCTION

Impaired NO-mediated vascular relaxation in diabetes may also arise from abnormalities in signal transduction due to decreased expression of inhibitory G proteins, reduced phosphoinositol metabolism, and increased activation of

protein kinase C (Gawler *et al.*, 1987; Greene *et al.*, 1987; Lee *et al.*, 1989). Increased activation of protein kinase C may occur by increased synthesis of diacylglycerol under hyperglycemic conditions (Lee *et al.*, 1989). The abnormal NO-mediated relaxation obtained in this way may in part be due to an increased production of vasoconstrictor prostanoids (see later) (Tesfamariam *et al.*, 1991).

TETRAHYDROBIOPTERIN AVAILABILITY

As discussed above, tetrahydrobiopterin is a cofactor for NO synthase. In low concentrations of this cofactor, NO synthase is known to produce less NO and, correspondingly, enhanced quantities of the oxidant species hydrogen peroxide (H_2O_2). An exogenous tetrahydrobiopterin derivative (6-methyl-5,6,7,8-tetrahydropterin) improves eNOS activity in diabetic endothelium. Thus, also tetrahydrobiopterin availability can play a role in the regulation of NO production by diabetic endothelium (Pieper, 1997).

GENERATION AND RELEASE OF VASOCONSTRICTOR PROSTANOIDS THAT COUNTERACT THE EFFECT OF NO

In the aorta from diabetic rabbits impaired relaxations to ACh are restored by inhibitors of cyclooxygenase. Moreover, the release of thromboxane A_2 and prostaglandin E_2 is significantly increased in this model. Therefore, these contractile prostanoids could counteract NO-mediated relaxations (Mayhan, 1989; Tesfamariam *et al.*, 1989).

OXIDATIVE STRESS

As in atherosclerosis, reactive oxygen species are considered to play an important role in diabetes mellitus as well. In rats, diabetic endothelium produces increases in both superoxide anion and H_2O_2 leading to enhanced intracellular production of hydroxyl radicals (Pieper *et al.*, 1997b). It has been demonstrated that inactivation of endothelium-derived NO by oxygen-derived free radicals contributes to abnormal vascular reactivity in animal models of diabetes mellitus. However, at the onset of diabetes acute endothelium-mediated vasodilation is not impaired (Brands and Fitzgerald, 1998). Vasoactivity during acute hyperglycemia seems to depend on the superoxide anion scavenging properties of the vascular wall. In acute hyperglycemia and early stages of diabetes, radical scavenging capacity may be suitable to protect NO degradation, resulting in an enhanced vasodilation. In contrast, decreased free radical scavenging properties of the vasculature in prolonged hyperglycemia and in later stages of diabetes might promote NO degradation by an overshoot of superoxide anions, resulting in an attenuation of endothelium-dependent vasodilation (Graier *et al.*, 1997).

In diabetic patients, responses of angiographically normal coronary arteries to cold pressor test and to flow increase are impaired. Abnormal responses are not improved by L-arginine, suggesting that a deficit in substrate for NO synthesis is not involved. Deferoxamine restores a vasodilator response to the two tests, suggesting that inactivation of NO by oxygen species might be partly responsible for the impairment of coronary artery dilation in diabetic patients.

(Nitenberg *et al.*, 1998). Moreover, in patients with insulin-dependent diabetes mellitus, the antioxidant vitamin C selectively restores the impaired endothelium-dependent vasodilation in the forearm resistance vessels. Thus, NO degradation by oxygen-derived free radicals contributes to abnormal vascular reactivity in humans with insulin-dependent diabetes mellitus (Timimi *et al.*, 1998; Ting *et al.*, 1996).

Another way in which oxidative stress can be enhanced in diabetes involves the polyol pathway. Under hyperglycemic conditions, one-third of the metabolism of glucose is shunted through this pathway, in which glucose is metabolized first to sorbitol by aldose reductase and subsequently to fructose by sorbitol dehydrogenase. This polyol pathway may increase oxidative stress since aldose reductase activity may deplete NADPH, which is required for the antioxidant activity of glutathione reductase (Gonzalez *et al.*, 1986).

In diabetic patients impairment of endothelial function occurs even under normocholesterolemic conditions with normal LDL levels (Cohen, 1993). An important metabolic effect of diabetes mellitus is glycation of lipoproteins: LDL, like other proteins, are nonenzymatically glycated. Glycation of LDL occurs under hyperglycemic conditions in a time and glucose concentration-dependent way and favors the oxidation of LDL (Kawamura *et al.*, 1994). Glycated and oxLDL impairs endothelium-dependent vascular relaxations more potently than oxLDL, most likely due to increased formation of superoxide anions, resulting in inactivation of NO (Galle *et al.*, 1998). This mechanism may be relevant to the high prevalence of vascular disease, including atherosclerosis and microangiopathy, that occurs in diabetic patients. NO may indeed inhibit platelet aggregation, monocyte adhesion to endothelial cells, and vascular smooth muscle cell proliferation. Nonenzymatic glycation of LDL is not identical with formation of advanced glycation end products (AGEs). AGEs arise from glucose-derived Amadori products at a later state during the glycosylation process (Bucala and Vlassara, 1995). These products have been shown to inactivate NO *in vitro* (Bucala *et al.*, 1991). Furthermore, high glucose and AGEs suppress constitutive NO synthase expression in retinal vascular endothelial cells (Chakravarthy *et al.*, 1998).

Therapy

Exercise training, but not food restriction, prevents endothelial dysfunction in NIDDM rats, presumably due to the exercise-induced increase in the production of NO (Sakamoto *et al.*, 1998).

In IDDM patients acute administration of the ACE inhibitor, enalaprilat, enhances NO-mediated endothelial function, with further improvement evident after 4 weeks of enalapril therapy (O'Driscoll *et al.*, 1997).

Gliclazide and glibenclamide, two therapeutic agents belonging to the group of sulfonylureas, are commonly used in the treatment of diabetes. They effectively reduce blood sugar in NIDDM by augmenting insulin release. In addition,

gliclazide scavenges superoxide anions, hydroxyl radicals, and NO in a dose-dependent manner, whereas glibenclamide is without effect. Thus, gliclazide not only is effective in reducing blood sugar, but also may be beneficial by inhibition of lipid and protein denaturation, which leads to the development of diabetic complications (Noda *et al.*, 1997).

Implications of Endothelial Dysfunction in Diabetes

The fact that diabetes mellitus is associated with early development of cardiovascular complications may be related to impaired NO-mediated vascular endothelial dysfunction. Furthermore, in women with gestational diabetes, maternal vascular endothelial dysfunction may contribute to the increased incidence of cardiovascular disorders (Knock *et al.*, 1997). The reduced blood flow and increased vascular resistance observed in diabetic pregnancies may be due to decreased NO synthesis and activity in the stem villous vessels which are the major determinants of resistance in the fetal-placental vasculature (Dollberg *et al.*, 1997).

Endothelial dysfunction in diabetes may also lead to sexual impotence. Penile erection is a neurovascular event, requiring relaxation of the trabecular muscle of the corpora cavernosa, which has been shown to be mediated by NO (Holmqvist *et al.*, 1991). The formation of NO and prostacyclin (PGI₂), and adenylyl cyclase activity but not guanylyl cyclase, are impaired in the corpus cavernosum of diabetic rabbits. Because NO and PGI₂ are produced by the endothelium, these studies consolidate the view that endothelial dysfunction is a major contributor to erectile dysfunction in diabetes mellitus (Sullivan *et al.*, 1998). These findings may provide a rationale for new types of treatment of diabetic men with impotence (Wennmalm, 1994).

Endothelial Dysfunction in Heart Failure

Another disease that is associated with endothelial dysfunction, including impaired flow-dependent endothelium-mediated dilation, is chronic heart failure (Drexler, 1998). In a model of heart failure in dogs expression of eNOS is reduced (Smith *et al.*, 1996). There is also evidence that chronic heart failure is associated with increased oxidative stress, which is apparently due to increased superoxide production by mitochondria and NADH oxidoreductases (Belch *et al.*, 1991). The antioxidant vitamin C improves endothelial dysfunction in patients with chronic heart failure (Hornig *et al.*, 1998a). Furthermore, in patients with chronic heart failure the ACE inhibitor quinapril, which has a high affinity for tissue ACE, improves flow-dependent endothelium-mediated dilation as the result of increased availability of NO. The ACE-inhibitor enalapril, which has a low affinity to tissue ACE, does not show this effect (Hornig *et al.*, 1998b). Also physical training improves the impaired endothelium-dependent relaxations in patients with chronic heart failure (Hornig *et al.*, 1996). This seems to be related to repetitive increases in blood flow and consequently intermit-

tent enhanced shear stress leading to an increased expression and activity of eNOS (Nishida *et al.*, 1992; Sessa *et al.*, 1994), upregulation of the radical scavenger enzyme Cu/Zn superoxide dismutase (Inoue *et al.*, 1996), and a decreased expression of ACE (Rieder *et al.*, 1997).

Age and Gender

Also age and gender play a role in vascular endothelial dysfunction. Endothelium-dependent vasodilation in forearm resistance vessels declines steadily with increasing age in healthy human subjects. Age is a strong univariate and multivariate predictor of endothelium-dependent vasodilation. This finding may be a marker for more widespread endothelial dysfunction (Gerhard *et al.*, 1996). Using forearm blood flow measurements it was shown that in normotensive and hypertensive humans, similar mechanisms, including dysfunction of the NO pathway and production of cyclooxygenase-dependent vasoconstrictors, cause age-related impairment of endothelium-dependent vasodilation. Only their earlier appearance characterizes hypertensive disease. Therefore, the endothelial dysfunction that occurs in hypertension seems to represent an accelerated form of dysfunction that occurs in aging (Taddei *et al.*, 1997).

Basal release of NO is larger in female animals than in males (Hayashi *et al.*, 1992). In cholesterol-fed rabbits the impairment of endothelium-dependent vasorelaxation is dependent on gender. A cholesterol-rich diet induces a more severe impairment of maximal relaxation to ACh in males compared to females, which may be due to a greater degradation of extracellular NO in the vessels wall of males (Kojda *et al.*, 1998). Moreover, intimal thickening following balloon denudation (White *et al.*, 1997), cuff placement (Akishita *et al.*, 1997; Moroi *et al.*, 1998), or feeding a cholesterol-rich diet (Hayashi *et al.*, 1995) are always smaller in female animals as compared to males. Although the precise mechanism for the slower rate of development of atherosclerosis in female rabbits is not completely clear, the greater basal release of NO in females before they were fed a hyperlipidemic diet, besides other factors, may be involved.

Endothelial dysfunction has also been found to be less severe in female than in male SHR, which could contribute to the gender differences observed in the extent and rate of progression of hypertension in SHR. Release of cyclooxygenase-derived constricting factors appeared to be more pronounced in male than in female SHR. In addition, the relative role of NO in endothelium-dependent arterial relaxation seemed to be higher in female than in male SHR, and relaxation induced by an NO donor also was more pronounced in female than in male SHR (Kahonen *et al.*, 1998).

Endothelium-Derived Hyperpolarizing Factor and Its Interaction with NO

Rudi Busse and Ingrid Fleming

Institut für Kardiovaskuläre Physiologie, Klinikum der JWG-Universität Frankfurt, Germany

LOCAL VASCULAR TONE IS GENERALLY DETERMINED BY EXTRINSIC AND INTRINSIC MECHANISMS SUCH AS AUTONOMIC NERVE ACTIVITY, CIRCULATING VASOACTIVE COMPOUNDS, TISSUE METABOLITES, THE MYOGENIC RESPONSE, AND ENDOTHELIUM-DERIVED AUTACOIDS. THE BEST CHARACTERIZED AUTACOIDS ARE THE POTENT VASODILATORS NITRIC OXIDE (NO) AND PROSTACYCLIN (PGI₂) AND THE VASOCONSTRICTOR PEPTIDE ENDOTHELIN. SEVERAL STUDIES HAVE, HOWEVER, CONVINCINGLY DEMONSTRATED THE EXISTENCE OF AN NO/PGI₂-INDEPENDENT COMPONENT OF ENDOTHELIUM-DEPENDENT RELAXATION IN VARIOUS ARTERIAL BEDS, MOST NOTABLY IN MESENTERIC, CAROTID, CORONARY, AND RENAL ARTERIES. SINCE THIS NO/PGI₂-INDEPENDENT VASODILATION WAS COINCIDENT WITH VASCULAR SMOOTH MUSCLE HYPERPOLARIZATION, THE TERM ENDOTHELIUM-DERIVED HYPERPOLARIZING FACTOR, OR EDHF, WAS COINED. THIS CHAPTER IS INTENDED TO PROVIDE AN OVERVIEW INTO THE FIELD OF EDHF AND TO DELINEATE THE INTERACTION OF NO WITH THE ONLY WELL-CHARACTERIZED EDHF, NAMELY, THAT GENERATED IN THE CORONARY AND RENAL VASCULATURE.

Relationship between Membrane Potential and Relaxation

Hyperpolarization and Relaxation

The mechanism by which hyperpolarization elicits relaxation is controversial. The most direct and obvious explanation is that hyperpolarization of the smooth muscle cell membrane reduces the open probability of voltage-dependent Ca²⁺ channels, activates Ca²⁺ sequestration and removal mechanisms so that smooth muscle [Ca²⁺]_i is lowered, and relaxation can take place.

Although this mechanism may operate in some vascular preparations, it is not universal. For example, the rabbit thoracic aorta is not depolarized during contraction induced by

norepinephrine and the contraction induced is minimally affected by Ca²⁺ entry blockers such as nifedipine. Nevertheless, under such conditions K⁺_{ATP} channel openers are potent relaxants, indicating that the opening of K⁺ channels may also induce relaxation by mechanisms other than inhibition of voltage-dependent Ca²⁺ channels. However, although hyperpolarization is not always essential for relaxation, it may be determinant in systems in which NO/cyclic GMP production is attenuated or inhibited.

Endothelium-Dependent Smooth Muscle Cell Hyperpolarization

Receptor-dependent Ca²⁺-elevating agonists (e.g., acetylcholine, bradykinin, substance P, histamine, ADP, and

endothelin) stimulate endothelial cells and induce the hyperpolarization of vascular smooth muscle cells. As this response is resistant to nitric oxide synthase (NOS) and cyclooxygenase (COX) inhibitors it is generally attributed to the release of an EDHF.

While the definition of EDHF implies that a factor released from the endothelium hyperpolarizes vascular smooth muscle cells, many studies have been performed in organ chambers without the concomitant measurement of membrane potential. Thus, in a large number of the investigations performed to elucidate the nature of EDHF, the predominant factor studied may be an as-yet-unidentified endothelium-derived relaxing factor (EDRF), that is, a nonhyperpolarizing NO/PGI₂-independent factor.

Under normal physiological conditions, the time course of smooth muscle hyperpolarization is more transient than that of relaxation. Under conditions of NOS/COX inhibition, a situation in which agonist-induced endothelium-dependent relaxation is thought to be mediated by the EDHF-induced hyperpolarization of smooth muscle cells, relaxations are much more transient than those mediated by NO and have a time course similar to that of hyperpolarization (Fig. 1). Such observations could indicate a cause-and-effect relationship.

The range of membrane potentials in which an EDHF can be expected to open K⁺_{Ca} channels and markedly affect membrane potential is relatively narrow. Very negative membrane potentials, that is, potentials close to the equilibrium potential for K⁺, are unlikely to be influenced by the opening of K⁺_{Ca} channels. Conversely, in depolarized cells the conductance for K⁺ is already high and the opening of additional K⁺ channels is unlikely to exert much of an effect.

Smooth Muscle Cell Membrane Potential

The membrane potential is determined by ionic concentration gradients and permeabilities according to the Goldman equation. The transmembrane ion distribution in vascular smooth muscle cells is similar to other excitable cells. The diffusion of ions through the membrane is driven by their electrochemical gradient and the permeability coefficient (*P*), which represents the ease with which an ion diffuses through the corresponding channel. The relative permeability of the membrane to K⁺, Na⁺, Ca²⁺, and Cl⁻ is $P_K = 1 > P_{Cl} = 0.366 > P_{Ca} = 0.201 > P_{Na} = 0.037$; therefore, the membrane potential is mainly determined by the opening and closing of K⁺ and, to a lesser extent, Cl⁻ channels.

The resting membrane potential of smooth muscle cells in normal pressurized arteries and arterioles *in vivo* is between -55 and -35 mV, reflecting the fact that arteries exist in a partially contracted state from which they can constrict or dilate. The working point is therefore positioned in the steep, linear range of the activation curve and shifted well to the right of the working point in resting skeletal muscle (approximately -90 mV).

As the membrane potential determines the activation of voltage-dependent ion channels, the consequences of K⁺

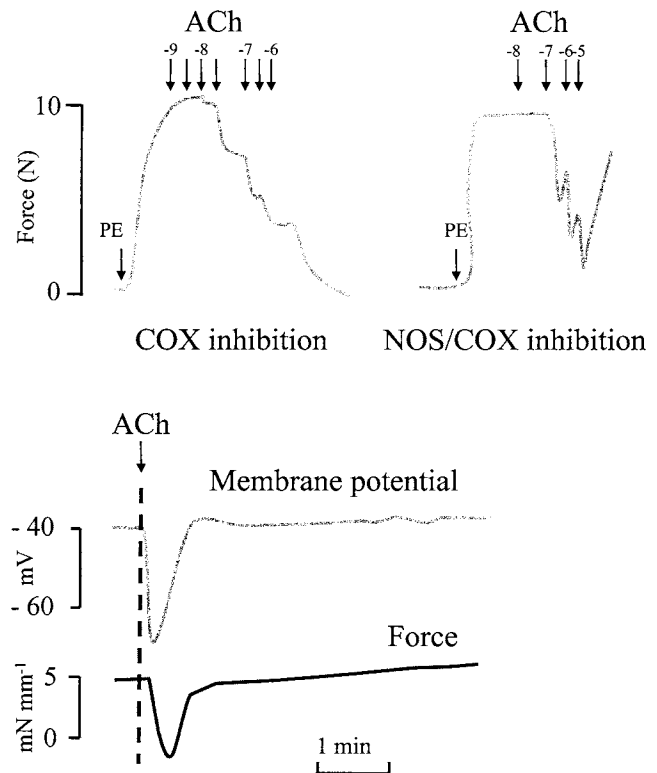

Figure 1 The kinetics of the NO- and EDHF-mediated relaxations of a mesenteric artery are distinct. Small mesenteric arteries, precontracted under isometric conditions with phenylephrine (PE), were relaxed by the cumulative addition of the Ca²⁺-elevating endothelial agonist acetylcholine (ACh). The top left tracing shows the response obtained when COX is inhibited and the relaxation is mediated mainly by NO, and the top right tracing shows the EDHF-mediated relaxation assessed in the presence of COX and NOS inhibitors. Lower tracings show the simultaneous changes in smooth muscle cell membrane potential and vascular tone in response to the application of a maximal concentration of ACh, in the presence of COX and NOS inhibitors.

channel gating (rate of opening) are thus twofold: (i) to set the membrane potential and influence the amplitude of inward Ca²⁺ currents that produce contraction and (ii) to carry the outward current that repolarizes the cell, thus modifying the kinetics of contraction.

The membrane potential is also affected by ion transporters. The activity of the Na⁺/K⁺ pump hyperpolarizes the plasmalemma, whereas the electrogenic Na⁺/Ca²⁺ exchanger also contributes to the membrane potential by translocating three Na⁺ ions into the cell and one Ca²⁺ out of the cell during each cycle.

The K⁺ permeability of the smooth muscle cell membrane is, in principle, determined by four different types of K⁺ channels, each of which has different characteristics and is activated under different conditions.

- Ca²⁺-activated K⁺ channels (K⁺_{Ca})
- ATP-sensitive K⁺ channels (K⁺_{ATP})
- Inwardly rectifying K⁺ channels (K⁺_{IR})
- Delayed rectifying voltage-dependent K⁺ channels (K⁺_{dr})

K^+_{Ca} channels are, as the name suggests, all activated by an increase in intracellular Ca^{2+} and are generally voltage-dependent. Vascular smooth muscle cells derived from the systemic circulation are somewhat depolarized, and $[Ca^{2+}]_i$ is slightly elevated; thus, it follows that outward current is carried to a large extent by K^+_{Ca} channels. The opening of only a very few K^+ channels is sufficient to bring about an effective membrane hyperpolarization, and thus K^+_{Ca} channels can hyperpolarize smooth muscle cells at low levels of activation. For example, the opening of only three K^+ channels in a cell containing 50,000 K^+ channels induces a membrane hyperpolarization of 2 mV. This weak hyperpolarization simultaneously decreases the open probability of voltage-dependent Ca^{2+} channels by approximately 30% and opposes the development of tension.

K^+_{Ca} channels are grouped into three main types according to their biophysical and pharmacological properties. Those channels exhibiting a large unitary conductance are often called “big” Ca^{2+} -dependent K^+ channels (BK_{Ca}) and are activated (i.e., open state probability increases) by increases in intracellular Ca^{2+} and membrane depolarization. Iberitoxin and noxiustoxin appear to be highly selective inhibitors of these channels in arterial smooth muscle cells. There are two other classes of K^+_{Ca} channels. Those exhibiting a much lower K^+ conductance are usually referred to as “small” K^+_{Ca} channels (SK_{Ca}) and are insensitive to charybdotoxin but are selectively blocked by apamin and scillatoxin. The other class is an intermediate or medium conductance, charybdotoxin-sensitive K^+_{Ca} channel (IK_{Ca}).

Three main groups of K^+_{Ca} :

Channel type	Conductance (pS)	Inhibitors
High conductance channel (BK_{Ca})	100–250	iberitoxin, noxiustoxin
Intermediate conductance channel (IK_{Ca})	20–60	charybdotoxin
Small conductance channel (SK_{Ca})	5–15	apamin, scillatoxin

K^+_{ATP} channels (conductance of 10–30 pS) are inhibited as the concentration of ATP at the internal membrane is increased. A fall in intracellular ATP may not be the most important physiological activator of these channels, which are also regulated by an increase in ADP, GDP, GTP, or an acidic pH. The antidiabetic sulfonylurea glibenclamide has been shown to selectively block K^+_{ATP} channels. On the other hand, a number of synthetic K^+_{ATP} channel openers, for example, cromakalim, effect vasodilation via membrane hyperpolarization following K^+_{ATP} activation.

Inwardly rectifying K^+ channels (conductance of 4–10 pS) are present mainly in small arteries and arterioles and exhibit an increasing conductance with membrane potentials steeply negative to the K^+ equilibrium potential. The inwardly rectifying channel closes when arterioles are tonically depolarized, so that the loss of K^+ ions during moderate depolarization is minimized.

Delayed rectifying voltage-dependent K^+ channels (conductance of 5–55 pS) facilitate an outward K^+ current in response to vascular smooth muscle hyperpolarization. The activity of these channels decreases on maintained depolarization, and therefore they act to repolarize the membrane potential. This again contributes significantly to the control of the membrane potential in resistance arteries.

WHICH K^+ CHANNELS ARE ACTIVATED BY EDHF?

Initially, it was generally assumed that EDHF activates K^+_{Ca} channels in vascular smooth muscle cells. The evidence for this is based on the following observations:

1. The EDHF-mediated vasodilation of an arterial bed in response to endothelial stimulation with a receptor-dependent agonist such as acetylcholine or bradykinin is associated with an increase in K^+ efflux, and the membrane conductance of smooth muscle is increased during hyperpolarization.

2. The EDHF-mediated vasodilation is inhibited by alterations in extracellular $[K^+]$ or other manipulations that influence the open probability of K^+ channels (Fig. 2).

3. K^+_{ATP} channel blockers (for example, glibenclamide) do not inhibit EDHF-mediated smooth muscle hyperpolarization and relaxation.

4. The endothelium-dependent hyperpolarization of vascular smooth muscle segments in intact vascular segments is sensitive to K^+_{Ca} channel inhibitors (such as apamin, charybdotoxin, or iberitoxin) but insensitive to inhibitors of K^+_{IR} or K^+_{ATP} .

5. In patch clamp bioassay systems, in which the membrane potential is monitored in smooth muscle cells positioned close to an endothelium-intact EDHF donor, the open probability of K^+ channels dramatically increases in response to an increase in Ca^{2+} , whereas decreasing intracellular Ca^{2+} blocks K^+ channel activity (Fig. 3).

It is important to keep in mind that both endothelial and smooth muscle cells possess a spectrum of ion channels, and none of the available inhibitors can differentiate between a target channel on endothelial cells and the same (or similar) target on smooth muscle cells. Indeed, although EDHF is generally reported to activate a K^+_{Ca} channel on smooth muscle cells, there is evidence to suggest that the K^+_{Ca} channel activated is an endothelial K^+_{Ca} channel. There are other observations which suggest that the K^+ channel activated by EDHF is not a typical BK_{Ca} channel. The classic BK_{Ca} channel is selectively inhibited by either iberitoxin or noxiustoxin. However, the characteristics of the channel activated by EDHF are somewhat different, and in most vascular beds, EDHF-mediated (i.e., NO/ PGI_2 -independent) relaxation and hyperpolarization are only partially sensitive to iberitoxin, charybdotoxin, or apamin but are abolished by the combination of charybdotoxin and apamin. Furthermore, the binding of charybdotoxin to a membrane preparation known to contain BK_{Ca} is unaffected by iberitoxin but is increased by apamin. This rather unexpected effect of apamin and charybdotoxin which is a characteristic of EDHF-mediated

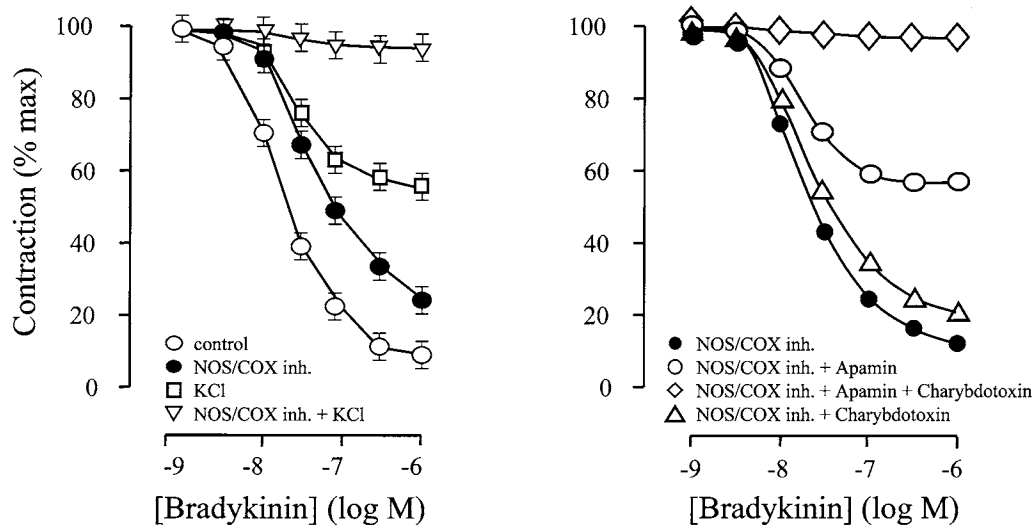

Figure 2 The EDHF-mediated vasodilation is inhibited by alterations in extracellular $[K^+]$ or other manipulations that influence the open probability of K^+ channels. Both graphs show concentration–relaxation curves to the Ca^{2+} -elevating endothelial agonist bradykinin obtained using contracted rings of porcine coronary artery. Relaxation was monitored under a number of conditions: control, in normal physiological salt solution conditions in which relaxation is mediated mainly by NO; NOS/COX inh., in the combined presence of COX and NOS inhibitors to reveal which proportion of the response is attributable to EDHF; KCl, in the presence of KCl (~ 40 mM), which is used to depolarize vascular cells and prevent hyperpolarization by EDHF; apamin, in the presence of apamin, an inhibitor of SK_{Ca} ; and charybdotoxin, in the presence of charybdotoxin, an inhibitor of IK_{Ca} . Complete inhibition of relaxation in the combined presence of apamin and charybdotoxin is a characteristic of EDHF-mediated responses in numerous arterial beds.

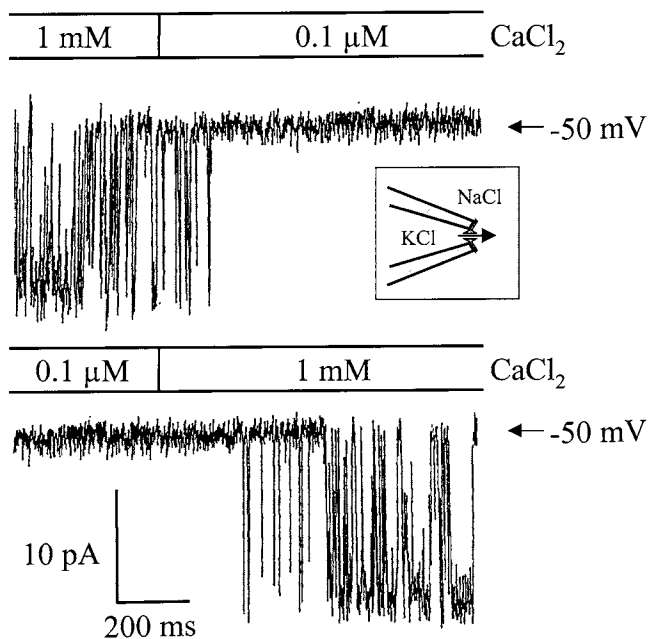

Figure 3 K^+_{Ca} channel opening in a membrane patch excised from a smooth muscle cell, stimulated by the EDHF-containing effluent from a bradykinin-stimulated porcine coronary artery in a patch clamp bioassay system. To demonstrate the Ca^{2+} dependency of these channels, the upper tracing shows the effect on channel current of decreasing the concentration of Ca^{2+} in contact with the excised patch. The lower tracing shows the opposite situation in which the K^+_{Ca} channel is activated by an increase in Ca^{2+} (modified from Popp *et al.*, 1996).

responses, could be an indication for the existence of a novel K^+_{Ca} channel in either endothelial or smooth muscle cells which is structurally related to the classic BK_{Ca} . Alternatively, the combination of these two K^+_{Ca} inhibitors may affect other cell signaling processes such as gap junctional communication (see below) or the activation of a key enzyme or effector kinase cascade.

EDHF AND ENDOTHELIAL CELL HYPERPOLARIZATION

Although endothelial cells are nonexcitable, the membrane potential remains an important determinant of endothelial cell function. Indeed, endothelial cells are hyperpolarized by many of the agents that elicit the hyperpolarization of vascular smooth muscle cells. Endothelial cell hyperpolarization has been attributed to the opening of K^+_{Ca} on the endothelial cell membrane, as a consequence of an agonist-induced increase in $[Ca^{2+}]_i$. Because endothelial cells lack voltage-dependent Ca^{2+} channels, the influx of Ca^{2+} into endothelial cells is determined mainly by the electrochemical gradient for Ca^{2+} . Endothelial hyperpolarization, which is a consequence of K^+ efflux via the K^+_{Ca} channel, counteracts the depolarizing effects of Ca^{2+} and enhances its driving force, thereby contributing to the sustained entry of Ca^{2+} . There is some evidence to suggest that EDHF may exert an autocrine effect on, and may be involved in regulating Ca^{2+} signaling in endothelial cells.

WHICH VESSELS HAVE A PROMINENT EDHF?

Not all arteries generate an EDHF or exhibit an NO/ PGI_2 -independent relaxation on agonist stimulation. A general

rule of thumb has been that the importance of EDHF as a vasodilator increases with decreasing vessel size. The reasons for this are currently unclear and are unlikely to be resolved until the EDHF-generating enzymes in each arterial bed have been characterized. There are at least three alternative explanations for the apparent predominance of EDHF-mediated relaxation in small arteries. The first is that these arteries have many more gap junctions than larger arteries. This hypothesis complements findings suggesting that myo-endothelial gap junctional communication plays a major role in EDHF-mediated relaxation of medium- and small-sized mesenteric arteries (see later). The second hypothesis states that EDHF-mediated relaxation is predominant in vessels in which contraction depends on the entry of Ca^{2+} into vascular smooth muscle cells through L-type Ca^{2+} channels. Indeed, the closure of L-type Ca^{2+} channels appears to be the major mechanism of EDHF-mediated relaxation. However, hyperpolarizing factors may also induce relaxation by additional mechanisms, probably including a reduction in the sensitivity of contractile elements to Ca^{2+} . The third, and most probable, explanation is that the endothelium of one vessel or vascular bed is not identical with that of another, and there are specific endothelial enzymes that are considered to be differentially expressed by the endothelium from one organ to the next. For example, the intracellular localization of eNOS differs in endothelial cells within the coronary system, as does the expression of cytochrome P-450 (CYP) enzymes.

Putative Nature of EDHF

IS EDHF A TRANSFERABLE HUMORAL FACTOR OR AN ELECTRICAL PHENOMENON ASSOCIATED WITH GAP JUNCTIONAL COMMUNICATION?

The existence of a humoral hyperpolarizing factor synthesized by endothelial cells was originally proposed on the basis of an endothelium-dependent hyperpolarization of vascular smooth muscle cells in an arterial segment. However, it has proved difficult to substantiate the release of a diffusible hyperpolarizing factor using classic bioassay techniques to detect the transfer of a biological mediator between two separate vascular preparations in close opposition. Evidence that an EDHF can be transferred from one vessel to another has been obtained in patch clamp bioassay systems by monitoring the membrane potential of detector vascular smooth muscle cells situated downstream from, and electrically isolated from, donor endothelial cells. It should be emphasized that, although it is possible to bioassay a hyperpolarizing factor, there has been no convincing demonstration of a transfer of a hyperpolarizing and relaxing factor other than NO and PGI_2 to date. Thus although the factor released from porcine coronary artery segments, for example, does hyperpolarize vascular smooth muscle cells, it is not necessarily identical to the factor responsible for the NO/ PGI_2 -independent relaxations.

The vascular endothelium contains microscopically identifiable gap junctions that allow metabolic communication

between cells and that are reportedly involved in the propagation of vasomotor signals along the vessel wall. There is evidence that, at least in small arteries, gap junctions exist between endothelial and smooth muscle cells—so-called myo-endothelial gap junctions. Such a direct pathway for cellular communication between endothelial and smooth muscle cells not only electrically couples these cells but also facilitates the rapid and direct transfer of signaling molecules such as inositol 1,4,5-trisphosphate, Ca^{2+} , and cyclic nucleotides.

Myo-endothelial gap junctions were initially described as unidirectional (i.e., dye transfer from smooth muscle to endothelial cells was marked, whereas there was little evidence to suggest the movement of dye in the opposite direction), but a bidirectional electrical transfer has since been demonstrated. There are also pronounced differences in data obtained in cultured cells and in intact arterial preparations, a fact most probably related to differences in the expression of connexin proteins *in situ* and *in vitro*.

The connexin proteins that form gap junctions have intracellular amino and carboxyl termini and four membrane spanning domains that form two extracellular loops and one intracellular loop. Connexins are assembled into hexamers or connexons somewhere between the endoplasmic reticulum (ER)-Golgi apparatus and the *trans*-Golgi network, prior to insertion into the plasma membrane. Connexons in one cell dock with connexons in adjacent cells through non-covalent interactions that involve the intracellular loops (Fig. 4). This arrangement facilitates the formation of an aqueous pore or channel (gap junction) which allows the passive intercellular exchange of small molecular mass molecules, ions, and second messengers (<1000 Da). The different connexin proteins build channels with unique functional properties, including differences in the size and charge of the molecules and ions that can transverse the channel. Channel gating can be modified by physiological parameters (such as pH and Ca^{2+}) and pharmacological agents (such as 12-*O*-tetradecanoylphorbol 13-acetate and retinoic acid).

The hypothesis that EDHF is, at least partially, a phenomenon which can be explained by electrical spreading through gap junctions may account for the inability of numerous investigators to assay the transfer of a factor which both hyperpolarizes and relaxes. Although other hypotheses have become more fashionable, the possibility that EDHF is in fact not a diffusible factor has remained in the background. The idea that gap junctional communication is involved in the manifestation of EDHF-mediated responses has recently been revived by observations showing that a number of compounds (such as 18 α -glycyrrhetic acid and heptanol) that uncouple gap junctions are able to attenuate EDHF-mediated relaxations (Fig. 5). Moreover, peptides raised against the extracellular loops of connexin 43 have been demonstrated to attenuate EDHF-mediated relaxations in the rabbit mesenteric artery. This process is thought to represent heterocellular coupling, as connexin 43 is rarely expressed in unstimulated native endothelial cells and is the major connexin in the endothelial-smooth muscle junction.

Figure 4 Model of a single connexon, consisting of six connexins (left), and a cluster of gap junctions (right).

Figure 5 Fluorescent dye coupling between endothelial cells in a confluent monolayer is evident under basal conditions, demonstrating the existence of a continual gap junctional communication. Uncoupling agents such as 18α-glycyrrhetic acid completely inhibit the cell-to-cell transfer of this dye. (Micrograph kindly provided by R. Brandes; reprinted by permission from Nature (399:601–605) © 1999 Macmillan Magazines Ltd.)

The possibility that EDHF is a substance that is capable of affecting gap junctional communication is not necessarily at odds with the observations made using bioassay models, as it is conceivable that this factor may spill over into the extracellular fluid.

Is NO AN EDHF?

High concentrations of NO have been reported to directly activate Ca^{2+} -activated K^+ (K_{Ca}^+) channels and to induce smooth muscle hyperpolarization under certain experimental conditions. However, whether physiological concentrations of NO are able to induce the hyperpolarization of vascular smooth muscle cells, which is generally attributed to the actions of EDHF, was initially controversial. While an NO/ PGI_2 -mediated hyperpolarization can be evidenced in patch clamp experiments, a significant portion (<60%) of the hyperpolarization elicited by the intraluminal solution from bradykinin-stimulated porcine coronary segments is insensitive to combined NOS/COX blockade. This residual hyperpolarization is unaffected by either oxyhemoglobin or selective soluble guanylyl cyclase inhibitors, which abrogate NO-mediated dilation. Moreover, the production of EDHF is actually inhibited by basally produced NO, and only under conditions of impaired NO synthesis can a distinct EDHF-like response be demonstrated. The most dam-

ing evidence against the “NO is an EDHF hypothesis” is the fact that agonist-induced activation of the endothelium induces a COX inhibitor-insensitive, charybdotoxin/apamin-sensitive vasodilation of microvessels in eNOS knockout mice, that is, mice lacking the eNOS gene (Fig. 6).

These considerations, taken together with the pharmacological characterization discussed later, clearly indicate that the endothelium-dependent hyperpolarization observed in response to agonists and mechanical stimulation is elicited by a hyperpolarizing factor that is distinct from NO and PGI_2 .

Is K^+ AN EDHF?

Small increases in the concentration of extracellular K^+ (within the range 6–20 mM) are known to elicit vasorelaxation and hyperpolarization by activating an inwardly rectifying K^+ current [$I_{\text{K}(\text{IR})}$] in smooth muscle cells. Although the K_{IR}^+ channel is not ubiquitously expressed, it has been proposed that in some arteries K^+ may be an EDHF that effluxes from endothelial cells through K_{Ca}^+ channels in response to agonist stimulation. The K^+ released in this manner would then accumulate in the myoendothelial space and activate both the K_{IR}^+ and the Na^+/K^+ -ATPase in smooth muscle cells, thereby inducing hyperpolarization (Fig. 7). Additional observations, showing that Ba^{2+} [which inhibits $I_{\text{K}(\text{IR})}$] and ouabain (an inhibitor of the Na^+/K^+ -ATPase) attenuate both K^+ - and acetylcholine-induced hyperpolarizations of rat mesenteric and hepatic arteries, were taken as evidence for K^+ being an EDHF. The combination of Ba^{2+} and ouabain, however, only induced a slight shift in the concentration–relaxation curve of these rat mesenteric arteries to both K^+ and acetylcholine, suggesting that the majority of the NO/ PGI_2 -independent relaxation is mediated by a completely different mechanism that may not be accompanied with a smooth muscle hyperpolarization.

Is ANANDAMIDE AN EDHF?

The endogenous cannabinoid anandamide was proposed to be an EDHF in rat mesenteric vessels. This hypothesis was based on the observation that a CB1 cannabinoid inverse agonist (a compound that inhibits the activity of a receptor which is basally active in unstimulated conditions),

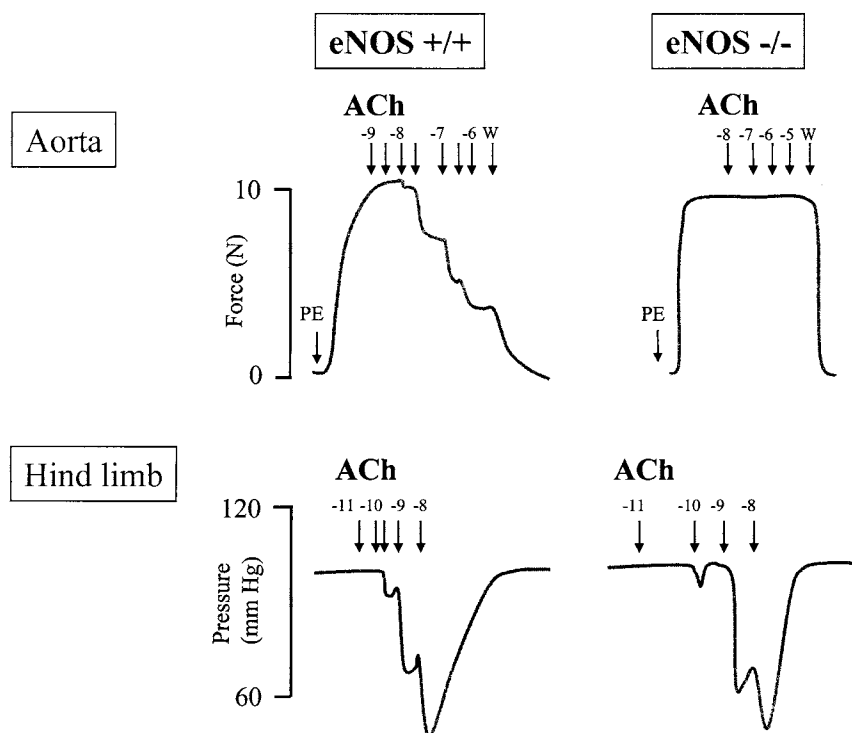

Figure 6 Tracings representing acetylcholine (ACh)-induced, endothelium-dependent relaxation of the aorta and vasodilation of hind limb arteries from control mice (eNOS +/+) and mice lacking the eNOS gene (eNOS -/-). Although in the aorta NO is the principal endothelium-derived relaxing factor and ACh cannot relax aortae from eNOS -/- mice, a comparable ACh-induced, endothelium-dependent vasodilation occurs in the hind limb of eNOS +/+ and eNOS -/- mice. (Tracings kindly provided by R. Brandes).

Figure 7 Scheme showing how K⁺ has been proposed to act as an EDHF. An agonist stimulates its receptor (R) on an endothelial cell and elicits the release of Ca²⁺ from intracellular stores as well as the influx of Ca²⁺ from the extracellular space. The resulting increase in endothelial [Ca²⁺], activates K⁺_{Ca} channels and thus K⁺ efflux from the endothelial cell. [K⁺] in the myo-endothelial space increases and activates both the K⁺_{IR} and the Na⁺/K⁺-ATPase in smooth muscle cells, thereby inducing hyperpolarization and relaxation (based on Edwards *et al.*, 1998).

attenuated relaxations mediated by “authentic EDHF.” However, although anandamide and additional CB1 agonists, such as Δ^9 -tetrahydrocannabinol, induce the relaxation of a range of vessels by a COX-dependent mechanism, these compounds do not induce an EDHF-like (NOS/COX inhibitor-insensitive, K^+_{Ca} channel-mediated) relaxation. The observed effects of anandamide may be attributed to the generation of additional arachidonic metabolites, including EETs, as anandamide can be enzymatically synthesized from, and may well prove to be a carrier of arachidonic acid, the putative precursor of EDHF. More recently, the CB1 inverse agonist used to apparently inhibit the generation of EDHF was reported to be a potent inhibitor of gap junctional communication.

IS EDHF AN ARACHIDONIC ACID METABOLITE?

The hyperpolarizing factor produced by coronary and renal arteries from humans, pigs, cows, dogs, rats, and rabbits displays characteristics similar to those of a cytochrome P-450 (CYP)-derived metabolite of arachidonic acid. This hypothesis was developed initially based on experimental observations showing that the application of exogenous arachidonic acid to isolated vascular segments induced relaxation. In addition, in many arteries EDHF-mediated responses were inhibited in the presence of compounds that inhibit phospholipase A_2 (PLA $_2$), the enzyme responsible for the liberation of arachidonic acid from membrane phospholipids. As EDHF and PGI $_2$ were known to be distinct, an arachidonic acid metabolizing enzyme distinct from COX was proposed to be responsible for the generation of EDHF. Therefore either a lipoxygenase or CYP product became a likely candidate.

That EDHF may be a CYP-dependent metabolite of arachidonic acid was implied on the basis of the fact that CYP inhibitors, such as clotrimazole, miconazole, and 17-octadecynoic acid, markedly attenuated EDHF-mediated hyperpolarization and relaxation in a number of vascular preparations. However, these conclusions were limited by the facts that these CYP inhibitors cannot discriminate between different CYP isoforms (over 300 isozymes have been reported), and can directly interfere with K^+ channels, which are the main cellular targets of EDHF. The CYP products proposed to be EDHFs were the epoxyeicosatrienoic acids (EETs) 5,6-EET, 8,9-EET, 11,12-EET, and 14,15-EET (Fig. 8). Indeed, EETs are generated by endothelial cells and mediate part of the dilator effect of arachidonic acid. 11,12-EET and 5,6-EET induce K^+_{Ca} channel inhibitor-sensitive relaxations of endothelium-denuded arteries and activate large conductance K^+_{Ca} channels in native and cultured smooth muscle cells (Fig. 9).

It is only more recently that convincing evidence for the existence of a CYP-derived EDHF has been provided. Coronary endothelial cells have been found to express CYP epoxygenases (EET-producing CYP isozymes) including CYP 2C8, CYP 2C9, and CYP 2J2. Enhancing the expression of the CYP 2Cs using β -naphthoflavone enhances the

Figure 8 Structure of the epoxyeicosatrienoic acids (EETs), 5,6-EET, 8,9-EET, 11,12-EET, and 14,15-EET, synthesised from arachidonic acid by cytochrome P-450 (CYP) epoxygenases.

synthesis of 11,12-EET by endothelial cells, as well as EDHF-mediated hyperpolarization and relaxation of intact arterial segments. Perhaps the most convincing evidence obtained to date that the EDHF synthase in porcine coronary arteries is a CYP enzyme has been provided using antisense oligonucleotides against the coding region of CYP 2C8. Incubation of porcine coronary arteries with antisense, but not sense or scrambled, oligonucleotides markedly attenuated bradykinin-induced, EDHF-mediated relaxation without affecting responsiveness to endogenously produced NO or an NO donor (Fig. 10). This inhibitory effect of antisense oligonucleotides provided the first nonpharmacological evidence that the EDHF produced by porcine coronary arteries is a CYP-dependent metabolite of arachidonic acid, or that a CYP metabolite is an essential permissive factor for EDHF-mediated vascular responses.

The reason for the caution in stating that the coronary EDHF is an EET is that it is currently unclear how endothelium-derived EETs are able to access smooth muscle cells to elicit hyperpolarization. EETs are by nature lipophilic, and simple diffusion from the endothelium to the media down a concentration gradient would be too slow to account for the rapidly initiated EDHF-mediated hyperpolarization and relaxation. One possibility, which would also link many of the observations made in different vessels, is that EETs are able to either pass through gap junctions or influence gap junctional communication of a second hyperpolarizing agent.

It must be stressed, however, that although the evidence that EDHF-mediated responses in the coronary and renal artery require the generation of an EET, several different EDHFs exist in different species. For example, the hyperpolarizing factors released from the human gastroepiploic artery, guinea pig carotid and rat mesenteric and hepatic arteries, or the rat portal vein exhibit pharmacological characteristics clearly distinct to those of the “CYP-related EDHF.”

Figure 9 Scheme showing how epoxyeicosatrienoic acids (EETs) have been proposed to act as an EDHF. An agonist stimulates its receptor (R) on an endothelial cell and elicits the release of Ca^{2+} from intracellular stores as well as the influx of Ca^{2+} from the extracellular space. The resulting increase in endothelial $[\text{Ca}^{2+}]_i$ activates the phospholipase A_2 (PLA_2) which liberates arachidonic acid (AA), the substrate for the cytochrome P-450 2C (CYP 2C) isoform which is the EDHF synthase in coronary arteries. The EETs formed then activate K^+_{Ca} channels on vascular smooth muscle cells to induce hyperpolarization, inhibit voltage-dependent Ca^{2+} channels, and attenuate $[\text{Ca}^{2+}]_i$, thus inducing smooth muscle relaxation.

Figure 10 EDHF-mediated hyperpolarization and relaxation of the porcine coronary artery are inhibited by decreasing cytochrome P-450 2C (CYP 2C) protein using antisense oligonucleotides. (Left) Tracings represent the bradykinin-induced, EDHF-mediated hyperpolarization of artery smooth muscle cells following incubation with either CYP 2C sense oligonucleotides or CYP 2C antisense oligonucleotides. The antisense treatment selectively inhibits the generation of EDHF and does not affect the hyperpolarization produced by 11,12-epoxyeicosatrienoic acid (11,12-EET), a putative EDHF and CYP 2C product. (Right) Concentration-relaxation curves to bradykinin obtained using rings of porcine coronary artery incubated in the absence (CTL) and presence of either sense (Se), scrambled (Scr), or antisense (As) CYP 2C oligonucleotides. Only the CYP 2C As oligonucleotides attenuated EDHF-mediated relaxation. To be attributable to EDHF, hyperpolarization and relaxation were assessed under conditions of combined NOS/COX blockade (modified from Fisslthaler *et al.*, 1999).

Figure 11 The generation of EDHF is Ca^{2+} dependent, and the production of EDHF is more sensitive than that of NO to the removal of extracellular Ca^{2+} . The tracings illustrate acetylcholine (ACh)-induced dilation of the rabbit carotid artery following the removal of extracellular Ca^{2+} in the continuous presence of a COX inhibitor and in the absence (left) and presence (right) of a NOS inhibitor (L-NA, *N*^ω-nitro-L-arginine).

SUBCELLULAR LOCALIZATION OF THE CYP-LIKE EDHF SYNTHASE

Whereas the intracellular site of EDHF synthesis is likely to have a number of implications on its sphere of influence and thus biological activity, the cellular distribution of the EDHF-generating enzyme and the relationship between localization and enzymatic activity are unclear. Although CYP enzymes are synthesized on polyribosomes bound to the endoplasmic reticulum and are cotransitionally inserted into the endoplasmic reticulum membrane, their exact localization is thought to be isoform specific. There is an extensive flow of vesicles to the Golgi apparatus as well as a microtubule-dependent transport from the Golgi to the plasma membrane, and at least one CYP enzyme, CYP 2B, is thought to traffic between the Golgi apparatus and the plasma membrane. Although the subcellular localization of the endothelially expressed CYP epoxygenases that could generate EDHF (CYP 2C8/9 or CYP 2J2) remains to be elucidated, the fungal toxin brefeldin A, which disrupts the Golgi apparatus and Golgi-plasma membrane trafficking, inhibits the production of the CYP-dependent EDHF.

It is only possible to speculate on the mechanism by which brefeldin A inhibits EDHF synthesis. This mechanism, however, does not appear to be related to a decreased availability of arachidonic acid, as the lack of effect of brefeldin A on PGI_2 formation suggests that the liberation of arachidonic acid is not inhibited. Brefeldin A treatment does not result in the global inhibition of CYP activity, since this agent did not affect the ability of endothelial cells to dealkylate the substrate 7-ethoxyresorufin. Rather, the effects of brefeldin A on the trafficking of proteins between the endoplasmic reticulum, Golgi apparatus, and the plasma membrane may be responsible for the observed inhibition of EDHF release.

Signal Transduction Leading to Activation of the EDHF Synthase: The CYP-Related EDHF Synthase

Ca^{2+} Dependency

Given that the exact chemical identity of EDHF remains to be elucidated, it is difficult to investigate the signal transduction cascade that results in the activation of the “EDHF synthase.” Current opinion is that the synthesis of EDHF is secondary to the activation of PLA_2 and to the liberation of arachidonic acid. Indeed, the synthesis of EDHF is thought to be Ca^{2+} dependent by virtue of the reported Ca^{2+} dependency of PLA_2 . Thereafter, the signaling pathway is obscure, and although EDHF may be generated from arachidonic acid by CYP enzymes in some vascular beds, this is almost certainly not the case in others.

The Ca^{2+} dependency of EDHF production has been demonstrated in a number of experiments in which a maintained, extracellular Ca^{2+} -dependent hyperpolarization was demonstrated in response to the Ca^{2+} ionophore. The Ca^{2+} dependency of EDHF-mediated relaxations can be demonstrated by monitoring the vasodilator responsiveness to the repetitive administration of acetylcholine in the presence and absence of extracellular Ca^{2+} and NOS/COX inhibitors (Fig. 11). Such experiments reveal that the EDHF response is rapidly abolished following Ca^{2+} removal, whereas acetylcholine-induced NO production is more resistant. These observations are consistent with biochemical data reporting that the threshold requirement for Ca^{2+} is lower for eNOS than for PLA_2 .

The formation of a Ca^{2+} /calmodulin complex has also been proposed to be involved in the activation of the EDHF synthase as the calmodulin antagonist calmidazolium inhibits the EDHF-mediated hyperpolarization of smooth muscle

cells as well as EDHF-mediated relaxation in porcine and canine coronary arteries (Fig. 12).

Stimuli Resulting in the Production of EDHF

As EDHF-mediated hyperpolarization and relaxation is Ca^{2+} dependent, it is clear that the stimuli required to elicit an increase in the production of EDHF requires an increase in endothelial $[\text{Ca}^{2+}]_i$. The agonists generally used to elicit the synthesis of EDHF and to characterize its actions, for example, bradykinin, acetylcholine, and Ca^{2+} ionophores, induce marked changes in $[\text{Ca}^{2+}]_i$. Although some of these receptor-dependent agonists can be detected in the vicinity of the endothelium *in situ*, this generally occurs in proinflammatory situations. The physiologically relevant stimuli for the continuous generation of the endothelium-derived autacoids and the moment-to-moment regulation of local vascular tone are mechanical forces such as fluid shear stress and pulsatile stretch. Besides the continuously acting fluid shear stress, which is generated by blood flowing over the endothelial cell surface, the periodic distension and compression of arteries during the cardiac cycle (most prominent in coronary arteries), which is a direct consequence of the pumping action of the heart and the periodic ejection of blood into the arterial system, is known to enhance the formation of NO and PGI_2 .

The lack of a selective inhibitor of EDHF production has hampered the study of the physiological stimuli regulating the production of EDHF, but pulsatile changes in transmural pressure do result in a NOS/COX inhibitor-insensitive, K^+_{Ca}

channel inhibitor-sensitive increase in the compliance (distensibility) of coronary arteries, indicating that an EDHF mediates this response. It is highly plausible that the profile of EDHF release observed following the initiation of rhythmic vessel distension is determined by mechanically stimulated increases in the endothelial $[\text{Ca}^{2+}]_i$, and that peak and steady-state levels of EDHF production mirror endothelial Ca^{2+} levels.

It is difficult to state whether or not changes in fluid shear stress are able to alter the generation of EDHF, as, at least in cultured endothelial cells, shear stress does not always elicit an increase in endothelial $[\text{Ca}^{2+}]_i$ that is large enough to activate PLA_2 and liberate the putative EDHF precursor, arachidonic acid. It is possible, however, that shear stress induces more pronounced alterations or oscillations in $[\text{Ca}^{2+}]_i$ in endothelial cells *in situ*. Indeed, spontaneous transient outward K^+ currents have been reported in shear stress-stimulated endothelial cells, and the combination of charybdotoxin and apamin significantly inhibited the EDHF-mediated component of the shear stress-induced relaxation of rat resistance mesenteric arteries.

Actions of the CYP-Dependent EDHF

Preformed Pools of EET

One distinctive feature of the EETs is their ability to become esterified to several glycerophospholipids, especially to phosphatidylcholine and phosphatidylethanolamine. This process involves the epoxidation of arachidonic acid (to generate the EET), ATP-dependent activation to the corresponding EET-CoA derivatives, and EET enantiomer-selective lysolipid acylation. Among the eicosanoids, the esterification of EETs is unique and may well be an indication that an intracellular pool of preformed EETs could exist within certain cells. Although such an EET processing has been proposed to exist in endothelial cells, the eventual effect on biological function is unclear. The biosynthesis of EET-containing cellular phospholipids may provide the molecular basis for some of the biological actions attributed to the EETs. Many of these biological activities can be interpreted in terms of the ability of the EETs to become incorporated into cellular lipids and consequently to alter cell membrane permeability and enzyme activity.

K^+_{Ca} Activation

EDHF and EETs are reported to activate K^+_{Ca} in numerous vascular preparations as well as in cultured vascular smooth muscle and endothelial cells. In smooth muscle cells, hyperpolarization is brought about by an increase in the conductance of K^+ and is abolished in the presence of depolarizing concentrations of KCl . As mentioned previously, inhibitors of K^+_{Ca} channels, especially the combination of charybdotoxin/apamin, virtually abolish the EDHF-mediated

Figure 12 EDHF-mediated relaxation of porcine coronary arteries is inhibited by the calmodulin antagonist, calmidazolium, consistent with the concept that an increase in endothelial $[\text{Ca}^{2+}]_i$ and the formation of a $\text{Ca}^{2+}/\text{CaM}$ complex is a prerequisite for the activation of the EDHF synthase.

hyperpolarization and relaxation, whereas glibenclamide, an inhibitor of K_{ATP}^+ , usually has no inhibitory effect. Patch clamp experiments performed in the cell-attached mode, that is, when the channel under investigation is shielded from the extracellular medium by the pipette, have shown that EDHF is still able to activate K_{Ca}^+ channels. Thus it would appear that this factor activates K^+ channels in an indirect manner, possibly involving membrane-associated second messengers. Indeed, EETs activate K_{Ca}^+ channels in coronary smooth muscle cells via a G_{α_s} -mediated mechanism (a phenomenon observed only in the presence of added GTP or GTP and ATP) and may alter the sensitivity of these channels to Ca^{2+} (Fig. 13). The activation of protein kinase A by 11,12-EET is reported to be an important mechanism responsible for afferent arteriole vasodilation, and there is evidence suggesting that K_{Ca}^+ channels are modulated by cyclic AMP and protein kinase A.

20-Hydroxyeicosatetraenoic acid (20-HETE), an ω -hydroxylation product of arachidonic acid catalyzed by the ω -hydroxylase (CYP4A4), has been proposed to be involved in the development of myogenic tone. 20-HETE is endogenously produced by smooth muscle cells from small renal and cerebral vessels and, once formed, increases smooth muscle tone by inhibiting large conductance K_{Ca}^+ channels,

inducing depolarization and increasing $[Ca^{2+}]_i$, probably by activating L-type Ca^{2+} channels (Fig. 14). It is tempting to speculate that the open probability of large conductance K_{Ca}^+ channels in renal arteries is determined by the balance in the vascular production of 20-HETE and EDHF/NO, and that EDHF and NO affect vascular tone by counteracting the 20-HETE-induced inhibition of K_{Ca}^+ channels.

EDHF-Mediated Regulation of $[Ca^{2+}]_i$ in Vascular Cells

The signal transduction cascade initiated following activation of endothelial cells by receptor-dependent agonists, such as bradykinin, is associated with an elevation in $[Ca^{2+}]_i$, characterized by a transient peak followed by a steady or oscillating plateau phase. The initial component reflects, at least in part, the inositol trisphosphate (IP_3)-mediated release of Ca^{2+} from intracellular stores, whereas the second phase is characterized by a more prolonged transmembraneous Ca^{2+} influx. These two components of the Ca^{2+} response are related in such a manner that the degree of intracellular store depletion determines the extent of the subsequent transmembraneous or "capacitative" Ca^{2+} influx. The essence of this model of Ca^{2+} entry is that the information about the IP_3 -mediated

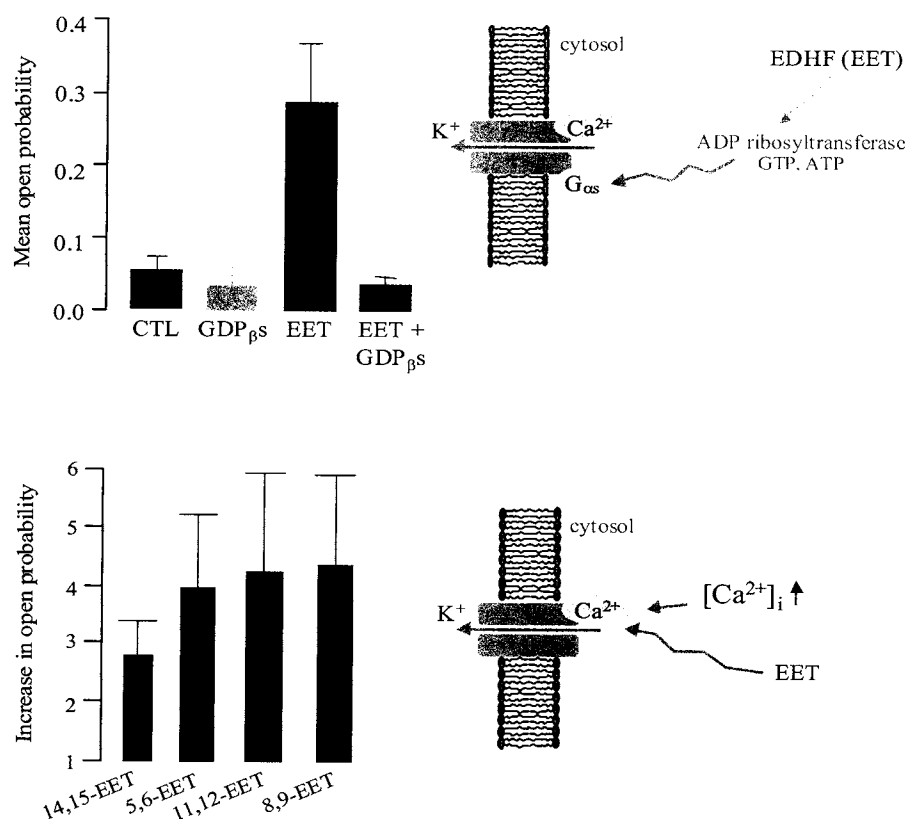

Figure 13 EDHF and EETs increase the open probability of K_{Ca}^+ channels in vascular cells by two mechanisms. The top panel shows that EETs activate K_{Ca}^+ channels via a G_{α_s} protein, possibly as a result of its ADP ribosylation, as the effect of the EET is prevented in the presence of the G-protein inhibitor GDP β S. The lower panel indicates that although K_{Ca}^+ channels are activated by an increase in cytosolic Ca^{2+} , EETs appear to enhance channel open probability at basal Ca^{2+} levels (modified from Li and Campbell, 1997, and Baron *et al.*, 1997).

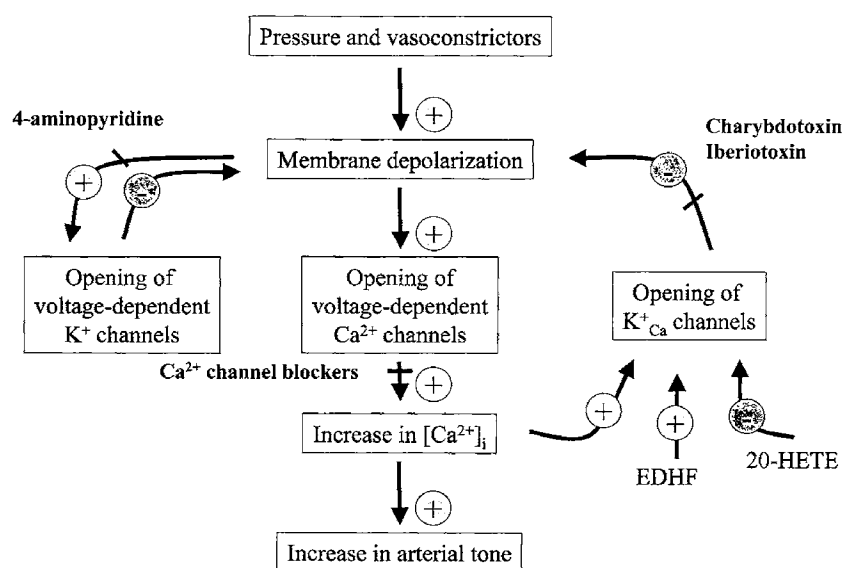

Figure 14 Mechanisms involved in the regulation of K^+_{Ca} channels and vascular tone. The open probability of large conductance K^+_{Ca} channels is determined by the balance of 20-hydroxy-eicosatetraenoic acid (20-HETE), and EDHF.

emptying of intracellular Ca^{2+} stores is transferred to the plasma membrane by one or more diffusible signal molecules that facilitate the activation of a pathway for store replenishment from the extracellular space. In principle, there are two ways by which an agonist can induce capacitative Ca^{2+} entry. The activation of the transmembraneous Ca^{2+} influx pathway could be attributed to an indirect effect, that is, instigation of capacitative Ca^{2+} entry following the mobilization of intracellularly stored Ca^{2+} , or a direct effect, that is, activation of a Ca^{2+} influx regulatory signaling molecule/protein.

Activation of CYP epoxygenases, the formation of EETs (especially 5,6-EET), and the subsequent tyrosine phosphorylation of cellular proteins may play a crucial role in regulating capacitative Ca^{2+} entry into endothelial cells. Indeed, endothelial CYP epoxygenases are activated by Ca^{2+} store depletion to produce products that hyperpolarize endothelial cells, and a number of CYP inhibitors and tyrosine kinase inhibitors selectively attenuate transmembraneous Ca^{2+} influx following agonist stimulation. Moreover, the induction of some CYP isoforms with dexamethasone and clofibrate enhances CYP activity, agonist-induced membrane hyperpolarization, and capacitative Ca^{2+} entry. There may also be a role for superoxide (O_2^-), which is a by-product of CYP activation, in endothelial Ca^{2+} signaling.

14,15-EET is also reported to enhance Ca^{2+} influx, but in this case into vascular smooth muscle cells, by activating voltage-dependent L-type Ca^{2+} channels. At first sight this observation completely contradicts the previously mentioned point that EETs inhibit L-type channels by inducing membrane hyperpolarization. However, the vascular smooth muscle response to the application of 14,15-EET is very much dependent on the state of contraction. Thus, an EET-induced contraction can be shown in segments maintained

under a passive tension, while only hyperpolarization and relaxation are detectable in precontracted vascular segments.

Activation of Protein Kinases by EDHF

By analogy with NO, which is a potent modulator of vascular gene expression, it is conceivable that the action of EDHF extends beyond its function as a vasodilator and is involved in the regulation of vascular cell proliferation.

CYP and lipoxygenase metabolites of arachidonic acid, including EETs, 20-hydroxyeicosatetraenoic acid (20-HETE), and 12(S)-HETE, activate the extracellular regulated protein kinases 1 and 2 (Erk1/2) and increase [3H]thymidine incorporation into various cell types, including vascular smooth muscle cells and endothelial cells. There is also evidence to suggest that the overexpression of the coronary EDHF synthase, CYP 2C8/9, in endothelial cells enhances cell proliferation. The precise steps between the activation of the EDHF synthase/CYP 2C8 and the initiation of cell proliferation remain to be elucidated, but the activation of Erk1/2 is more than likely to be a key step in this process, as the phosphorylation and activation of Erk1/2 are generally accepted to be essential for both migration and proliferation of vascular cells. 11,12-EET has also been reported to exert an anti-inflammatory effect in endothelial cells by inhibiting the activation of the transcription factor, nuclear factor- κB (NF- κB) and decreasing the cytokine-induced expression of adhesion molecules such as vascular cell adhesion molecule-1 (VCAM-1). Overexpression of CYP 2J2, another EET-generating epoxygenase, into bovine endothelial cells also attenuates the tumor necrosis factor α (TNF- α)-induced activation of NF- κB , although to a lesser extent than the exogenously applied EET. Such a difference may be accounted

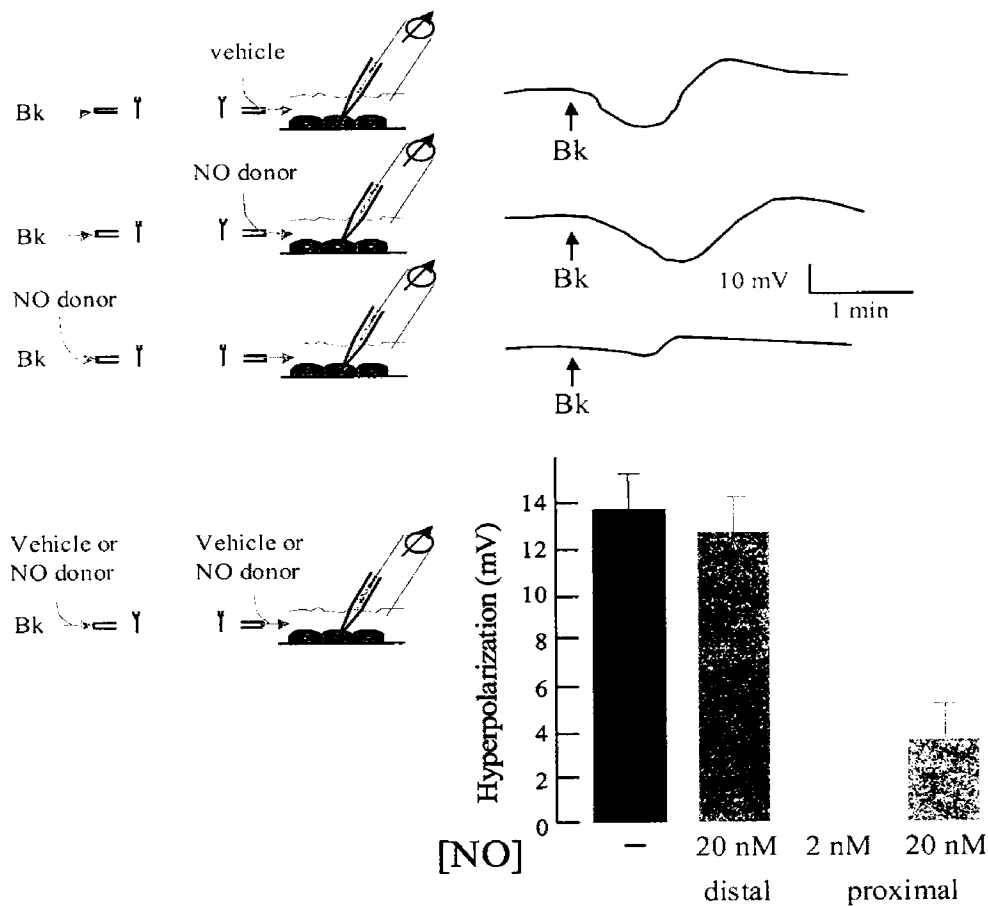

Figure 15 NO attenuates the synthesis of the CYP-dependent EDHF in a patch clamp bioassay, in which the generation of EDHF by a bradykinin (Bk)-stimulated artery is assessed as hyperpolarization of cultured vascular smooth muscle cells. (Top) As NO only inhibited EDHF-induced hyperpolarization when perfused with bradykinin through the donor artery, NO attenuates the production of EDHF rather than interfering with its ability to activate K_{Ca}^{+} channels on smooth muscle cells. (Bottom) The concentrations of NO that interfere with the generation of EDHF are very low and are equivalent to those produced by endothelial cells.

for by the fact that, in addition to EETs, CYP epoxygenases generate oxygen-derived free radicals, which also have marked effects on the activation of redox-sensitive transcription factors, including NF- κ B. Since there is a growing body of evidence to suggest that reactive oxygen intermediates can influence cell growth, it is feasible that some of the effects of CYP 2C overexpression can be attributed to the generation of CYP-derived free radicals.

Interactions between NO and EDHF

The interference of one endothelial autacoid with the synthesis of another is difficult to study, since a pure EDHF-mediated response can be observed only in the combined presence of NOS and COX inhibitors and, until relatively recently, no selective inhibitor of an EDHF synthase had been described. Given that EDHF-mediated responses are most prominent after NOS inhibition, it seemed logical to propose that the continuous production of physiological concentrations of NO by endothelial cells could dampen the generation of EDHF and/or the activity of the EDHF syn-

thase. Once again, since only the coronary EDHF synthase has been adequately characterized, the following discussion must be restricted to the CYP-like EDHF synthase.

NO attenuates the synthesis of the CYP-dependent EDHF, rather than interfering with its ability to activate K_{Ca}^{+} channels and elicit hyperpolarization. The EDHF-mediated hyperpolarization and relaxation of coronary arteries can be inhibited by very low concentrations of NO donor agents, which have been demonstrated to generate concentrations of NO similar to that produced by the stimulated endothelium (Fig. 15). Moreover, CYP activity in isolated microsomes and in endothelial cells can be abolished by NO donors. Several potential mechanisms have been proposed to account for the NO-induced inactivation of CYP enzymes, such as the liberation of heme from CYP proteins, inhibition of CYP protein synthesis, the reaction of NO with superoxide anions to form peroxynitrite (which in turn affects the nitration of critical amino acid residues), and the binding of NO to the heme moiety of CYP, forming nitrosyl-heme adducts, with subsequent oxidation of free thiols in CYP enzymes. In addition, since NO interacts with COX to enhance

Figure 16 Potential interactions between the CYP-like EDHF synthase/CYP-dependent EDHF and NO.

PGI₂ synthesis, NO may attenuate any basal EDHF production by channeling free arachidonic acid into prostanoid synthesis. A combination of several of the above mechanisms probably accounts for the NO-mediated inhibition of CYP-dependent EDHF production (Fig. 16).

On the whole, there is much evidence that the production of EDHF is attenuated by NO under physiological conditions and that this tonic inhibition is alleviated when NO synthesis is impaired so that EDHF can act as a back-up vasodilator system. A number of observations support this concept, including the finding that the generation of EET is markedly enhanced following the attenuation of bioavailable endothelium-derived NO and the induction of hypertension by salt loading. Also, the concentration CYP products produced by the vasculature is greater following endothelial injury in a model of coronary artery stenosis than in normal vessels. At this point it is necessary to stress that while NO can affect the production of the coronary type (CYP-dependent) EDHF, this is not necessarily the case for CYP-independent EDHFs, such as those detectable in the rat hepatic artery.

Although an EDHF can be detected in the perfused heart, mesentery, and hind limb of mice, it is currently unclear

whether or not this factor is related to a CYP-dependent metabolite of arachidonic acid. Thus any investigation into the interaction between EDHF and NO in mice lacking the eNOS gene must necessarily await the detailed characterization of the murine EDHF(s).

Role of Nitric Oxide in Myocardial Function

Jean-Luc Balligand,* Olivier Feron,* and Ralph A. Kelly†

**Division of Pharmacology and Therapeutics, Catholic University of Louvain, Brussels, Belgium, and*

†Cardiovascular Division, Brigham and Women's Hospital, Boston, Massachusetts

OVER THE PAST TWO DECADES, THE ROLE OF NITRIC OXIDE (NO) AND RELATED CONGENERS IN CARDIOVASCULAR PHARMACOLOGY HAVE LARGELY BEEN ELUCIDATED. IN THIS CHAPTER, WE FOCUS ON THE EXTRAVASCULAR PRODUCTION OF NO IN THE CONTROL OF CARDIAC CONTRACTILE FUNCTION. CARDIAC MUSCLE CELLS EXPRESS THE NO SYNTHASE ISOFORM ORIGINALLY DESCRIBED IN ENDOTHELIAL CELLS (eNOS OR NOS3), WHICH IS COUPLED TO BOTH β -ADRENERGIC AND M2 CHOLINERGIC RECEPTORS IN CARDIAC MYOCYTES, INCLUDING SPECIALIZED PACEMAKER AND CONDUCTION CELLS WITHIN THE HEART. THE MOLECULAR PHARMACOLOGY OF NO GENERATION IN CONTROL OF MYOCARDIAL CONTRACTILE FUNCTION BY THE AUTONOMIC NERVOUS SYSTEM IS DESCRIBED IN DETAIL, AS IS THE TARGETING OF eNOS TO CAVEOLAR MICRODOMAINS AND THE INTERACTIONS OF eNOS WITH CAVEOLIN-3. EVIDENCE POINTING TO THE PRESENCE OF ANOTHER NOS ISOFORM, POSSIBLY nNOS (NOS1), IN THE SARCOPLASMIC RETICULUM OF CARDIAC MYOCYTES, IS BRIEFLY REVIEWED. AS IN ALL TISSUES IN RESPONSE TO INFECTION, MANY CELL TYPES WITHIN THE MYOCARDIUM CAN EXPRESS iNOS (NOS2), AND THE IMPLICATIONS OF A ROBUST GENERATION OF NO BY iNOS IN RESPONSE TO SYSTEMIC SEPSIS OR LOCALIZED INFECTION ARE DESCRIBED. FINALLY, THE IMPLICATIONS OF THE OBSERVATION THAT iNOS IS ALSO EXPRESSED WITHIN THE INJURED OR FAILING MYOCARDIUM, IN THE ABSENCE OF EVIDENCE OF FOREIGN PATHOGENS, ARE CONSIDERED IN DETAIL.

Introduction

Autonomic neurotransmitters and hormones physiologically regulate the force and frequency of myocardial contraction. Norepinephrine and epinephrine, released by sympathetic nerves in the heart and by adrenal glands into the circulation, respectively, activate both α - and β -adrenergic receptors in cardiac muscle to increase myocardial contractility. Acetylcholine (ACh) released from parasympathetic nerves reduces contractility by binding to muscarinic cholinergic receptors, thereby opposing the action of catecholamines (Fig. 1). The proposal that nitric oxide (NO) produced endogenously within cardiac muscle regulates these two au-

tonomic nervous systems contributes a new dimension to our understanding of the molecular mechanism of action of neurotransmitters in the heart. It also offers potential new therapeutic approaches for disease states, such as heart failure in which autonomic nervous system function is abnormal.

We will briefly review the molecular pathways leading to the intracellular actions of β -adrenergic and muscarinic cholinergic agonists in the activation of endothelial nitric oxide synthase (eNOS), as well as cytokine activation of inducible NOS (iNOS), in the cardiac myocyte, integrating evidence that demonstrates that NO-dependent signaling can be shown both at the level of the isolated myocyte and in the intact animal.

Figure 1 Physiological regulation of cardiac contraction.

The β -Adrenergic Pathway

β -Adrenergic agonists increase both the force and frequency of contraction and the rate of relaxation of cardiac muscle. Despite some differences between regions of the heart, the immediate increase in the force of contraction is generally related to an increase in transmembrane flux of calcium through phosphorylation of the L-type Ca channel followed by the calcium-induced calcium release from the sarcoplasmic reticulum. The sustained inotropic effect during subsequent contractions results from the increased influx and mobilization of internal calcium resulting from an increased replenishing of calcium in the sarcoplasmic reticulum (Gibbons, 1986; Morad and Cleeman, 1987).

A hallmark of the β -adrenergic effect on the heart is to increase the rate of relaxation as well as increasing the force of contraction. This involves more rapid termination of calcium influx, increased rate of calcium uptake and sequestration into the sarcoplasmic reticulum following phospholamban phosphorylation (Katz, 1977, 1979), increased expulsion of intracellular calcium via sodium/calcium exchange (Sheu and Blaustein, 1986), and desensitization of contractile myofilaments to calcium (Stull, 1980; Robertson *et al.*, 1982).

β -ADRENERGIC RECEPTORS IN THE HEART

Although binding studies with selective ligands have identified two subtypes of β -adrenergic receptors in the heart (β_1 and β_2), the β_1 subtype usually predominates in the mammalian heart. In the rat heart, the percentage of β_1 subtype is 85%. The ratio of β_1 and β_2 differs in different regions of the human heart; for example, the percentage of β_1 is higher in ventricle than in atrium (Buxton *et al.*, 1987). Evidence was provided for the expression of β_3 adrenoreceptors (at the mRNA level) in biopsy specimens from human ventricles. Activation of this receptor with specific agonists (in the presence of β_1 and β_2 blockade) produced a unique negatively

inotropic effect on the contraction of human myocardium (Gauthier *et al.*, 1996).

THE CYCLIC AMP INTRACELLULAR PATHWAY

Stimulation of β_1 - and β_2 -adrenergic receptors increases cyclic AMP (cAMP) synthesis by stimulating the catalytic activity of adenylyl cyclase through a process involving GTP-binding regulatory proteins containing the α_s subtype. Adenylyl cyclase belongs to a family of enzymes that convert ATP to cyclic AMP that activates several target molecules; for example, cyclic AMP-dependent protein kinases regulate the activity of numerous downstream proteins. Although adenylyl cyclase isoforms are widely distributed, the only isoforms that have been definitively identified in ventricular heart tissue are types V and VI. As with all the other isoforms, these two types are also stimulated by G_{α_s} but are unaffected by either $\beta\gamma$ subunits or calcium/calmodulin unlike other adenylyl cyclase isoforms (Ishikawa and Homcy, 1997).

Like other isoforms, type V and VI adenylyl cyclases are inhibited by G_i -linked receptors. In addition, type VI adenylyl cyclase can be at least as effectively inhibited by elevations in intracellular calcium, providing a mechanism for the cross talk between calcium- and cyclic AMP-dependent signaling pathways, both important regulators of cardiac contractility.

CYCLIC AMP PHOSPHODIESTERASES

The levels of cyclic AMP are tightly regulated by a complex family of different phosphodiesterases (PDEs) widely distributed among various tissues, including the heart. Among the PDEs identified to date, members of at least seven families, PDE I, II, and III have been shown to be expressed in heart tissue. PDE I is regulated by calcium/calmodulin. PDE II contains a noncatalytic binding site with a high specificity for cyclic GMP. When cyclic GMP binds to this site, the affinity of the catalytic site is increased by allosteric interac-

tion. PDE II is therefore known as a cyclic GMP-stimulated phosphodiesterase. PDE II isoforms have been generally found to be expressed in tissues in which the effects of cyclic GMP are opposite to those of cyclic AMP. The expression of an isoform of PDE II in cardiac myocytes from several species, including rat (Bode *et al.*, 1991; Han *et al.*, 1998a), is an illustration of this principle.

In contrast, PDE III isoforms, also expressed in cardiac myocytes, are inhibited by cyclic GMP. In the heart, such inhibition by cyclic GMP would initially potentiate the increase in intracellular cyclic AMP with a resulting positive inotropic effect through an increase in L-type calcium current. The net result of an increase in cyclic GMP in heart muscle cells, however, is more difficult to predict given the coexpression of both PDE II and PDE III isoforms in the same myocytes (at least in the rat) (Bode *et al.*, 1991). The factors that determine whether there will be a potentiation or an attenuation of the effect of cAMP in heart muscle cells include the relative differences in affinity and V_{max} for this cyclic nucleotide between the two isoforms, and perhaps the subcellular localization of each PDE isoform, along with effector proteins for cAMP in the same subcellular compartment.

The Muscarinic Cholinergic Pathway

Molecular cloning has identified five muscarinic receptor subtypes named m1–m5 based on the order of their discovery (Bonner, 1989). Previous studies of the functional coupling of heterologously expressed receptors led to a distinction between isoforms that either mobilize intracellular calcium (m1, m3, and m5) or inhibit adenylyl cyclase (m2 and m4). However, this classification is somewhat arbitrary since there is ample evidence that m2 and m4 receptors do stimulate phospholipase C (through a pertussis toxin-sensitive G protein) and generate intracellular diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP_3) with subsequent liberation of calcium from the endoplasmic reticulum (Ashkenazi *et al.*, 1987). Additional evidence established that G protein $\beta\gamma$ couples m2 receptor stimulation to phospholipase C β_2 (Katz *et al.*, 1992).

INTRACELLULAR EFFECTORS FOR THE ACTION OF ACETYLCHOLINE IN THE HEART

Three main intracellular effectors account for most of the functional effects of acetylcholine in the heart: (1) activation of potassium channels, (2) inhibition of adenylyl cyclase, and (3) activation of soluble guanylyl cyclase leading to increases in intracellular cyclic GMP (which subsequently activates a number of downstream cyclic GMP-dependent effectors). A commonly held view is that the parasympathetic innervation predominantly influences the sinoatrial node and atrioventricular conducting systems in mammalian hearts, with little effect at the ventricular level. However, work using viral tracing experiments has also identified a rich distribution of vagal innervation throughout ventricular cavities (Standish *et al.*, 1994). Functionally, the effects of

acetylcholine are small in ventricular tissue in the absence of β -adrenergic stimulation, but when the heart is first stimulated with catecholamines, the effects of acetylcholine are greatly potentiated, a phenomenon that has been termed accentuated antagonism (Levy, 1977).

$I_{K(Ach)}$ In the sinoatrial node and in atrial muscle, accentuated antagonism is mostly accounted for by the activation by acetylcholine of a unique species of potassium channels, designated as $I_{K(Ach)}$, although the resulting K current is also affected by acetylcholine in the absence of catecholamine stimulation. This channel is variably distributed within the heart, with little representation at the ventricular level. In addition, the proportion between heart chambers varies according to species, with a ventricular $I_{K(Ach)}$ density of about 25% that of the atrium in the frog (Hartzell and Simmons, 1987). In other species, where the channel is present at very low levels in the ventricular muscle, alternative pathways must be involved in the antiadrenergic effects of acetylcholine.

Inhibition of Adenylyl Cyclase Among these pathways, the attenuation of adenylyl cyclase activity by muscarinic cholinergic receptors has been well documented in the heart (Murad *et al.*, 1962). The sensitivity of this effect to pertussis toxin indicates its mediation through $G_{i/o}$ proteins. This leads to a decrease in the generation of intracellular cyclic AMP, which results in a decline in the rate and force of cardiac contraction. Experiments in isolated myocytes from homozygous mice deficient in $G\alpha_o$, identified this as the essential isoform for muscarinic receptor coupling to the attenuation of I_{Ca-L} , at least in the mouse heart (Valenzuela *et al.*, 1997).

NO and Cyclic GMP The observation of a dissociation between the functional effects of acetylcholine and cyclic AMP levels (Watanabe and Besh, 1975; Keeley *et al.*, 1978; Löffelholz and Pappano, 1985) prompted the search for other second messenger pathways linked to muscarinic receptor stimulation. These have included the activation of guanylyl cyclase by muscarinic signaling to produce increases in intracellular cyclic GMP. Although a critical review of the early controversial evidence for the role of cyclic GMP as regulator of cardiac contractility is beyond the scope of this chapter, more recent experiments using exogenous NO donors or cyclic GMP analogs have now established the importance of this cyclic nucleotide in the control of cardiac contractility. As will be developed later in the chapter, most of the initial controversy regarding the importance of NO-dependent signaling in the regulation of cardiac function may have stemmed from now well-recognized variations in the observed effects among different regions of the heart and among different animal species, with the specific cardiac muscle preparation employed, and on the concentration of the NO donor or cyclic GMP applied.

Despite clear evidence that acetylcholine increases cyclic GMP levels in heart tissue, the coupling of any muscarinic cholinergic receptor to activation of soluble guanylyl cyclase in ventricular myocytes has until relatively recently re-

mained poorly understood. Interestingly, Goldberg and Had-dox had suggested in 1977 that the intracellular levels of calcium could regulate guanylyl cyclase activation. What was missing was the connection between elevation of intracellular calcium and activation of a guanylyl cyclase. Our demonstration of the constitutive expression of a calcium-sensitive isoform of nitric oxide synthase within human and rat ventricular myocytes supported the hypothesis that the parasympathetic regulation of cyclic GMP content in the heart is mediated by nitric oxide synthase (Balligand *et al.*, 1993a, 1995). Thus, muscarinic cholinergic receptor-mediated increases in intracellular IP₃ content, with an elevation in intracellular Ca²⁺, would result in activation of a calcium-regulated NO synthase.

In the following sections, we will briefly review the data characterizing the identity of the isoforms of NO synthase expressed in heart muscle, which support a functional role for endogenously produced nitric oxide in regulating the contractile response to β -adrenergic and muscarinic cholinergic stimulation, both in whole heart and in isolated ventricular myocyte preparations.

NOS Isoforms in Heart Muscle

There is now ample evidence that all three isoforms of nitric oxide synthase [neuronal NOS (nNOS), iNOS, and eNOS each encoded by a different gene, *NOS1*, *NOS2*, and *NOS3*, respectively] are expressed within various cell types in the myocardium (Fig. 2).

nNOS

Both cholinergic and nonadrenergic, noncholinergic nerve terminals were shown to express nNOS, as well as specialized conduction tissue and sympathetic nerve terminals of the guinea pig heart (Schmidt *et al.*, 1992; Tanaka *et al.*, 1993). Cardiac myocytes, however, do not seem to express the canonical nNOS, at least in the rat (Balligand *et al.*, 1995;

Belhassen *et al.*, 1996), or the muscle specific isoform of nNOS (nNOS-m; Silvagno *et al.*, 1996; Belhassen *et al.*, 1996). A protein with apparent immunoaffinity for anti-nNOS antibodies, but of a slightly different molecular weight, was identified in the sarcoplasmic reticulum of rabbit cardiomyocytes (Xu *et al.*, 1999). These observations await confirmation.

eNOS

eNOS is expressed in endothelial cells from the endocardium and from arterial capillaries and veins of all mammalian species to date, including humans (Andries *et al.*, 1998; Gauthier *et al.*, 1998a; Balligand and Smith, 1997; Balligand and Cannon, 1997). In addition, there is now unequivocal evidence that eNOS is expressed in cardiomyocytes from atrial, atrioventricular nodal, and ventricular myocytes in most mammalian species (Balligand *et al.*, 1995; Han *et al.*, 1996; Seki *et al.*, 1996) including humans (Wei *et al.*, 1996; Gauthier *et al.*, 1998a; Balligand and Smith, 1997). In cardiac myocytes as in endothelial cells, palmitoylated and myristoylated eNOS is localized to detergent-insoluble glycosphingolipid-rich microdomains of the plasmalemma termed caveolae (Feron *et al.*, 1996). The presence of specific caveolin-binding domains within eNOS allows direct protein-protein interaction between the enzyme and the respective cell-specific caveolin isoform, namely, caveolin-3 in cardiomyocytes and caveolin-1 in endothelial cells (Michel *et al.*, 1997; Garcia-Cardena *et al.*, 1997; Ju *et al.*, 1997). Notably, caveolin-3 was shown to be expressed in the T-tubular system in cardiac muscle, which had been suggested for years to develop from the coalescence of clusters of caveolae at the sarcolemmal membrane (Ishikawa, 1968). Altogether, these observations add weight to the suggestion of a potential role of eNOS in the regulation of excitation-contraction coupling in the heart.

iNOS

Virtually all cell types within the myocardium can express iNOS on appropriate stimulation with specific combinations of inflammatory cytokines or of lipopolysaccharide (LPS) *in vivo*. These include cardiac microvascular endothelial cells, cardiac myocytes, neurons, vascular smooth muscle cells, and infiltrating inflammatory cells (for a review, see Balligand and Cannon, 1997). The relative abundance of iNOS expression within each cell type *in vivo* may be substantially different from the results observed after exposure of cultured cells to recombinant cytokines *in vitro*. In addition, immunostaining for iNOS in the myocardium is not only spatially heterogeneous but also discontinuous over time, which may explain some of the discrepancies between published reports, especially in human tissue. Finally, the relative expression of iNOS in parenchymal cells versus infiltrating monocytes varies significantly according to the etiology of the cardiomyopathy; for example, between septic, transplant rejection, ischemic, or dilated cardiomyopathies. In human dilated cardiomyopathic hearts, iNOS protein has

Figure 2 NOS isoforms in the heart.

Figure 3 NOS in cardiac myocytes.

been colocalized with tumor necrosis factor (TNF- α), which along with other inflammatory mediators [i.e., interleukin (IL-1, IL-6, γ -interferon (IFN- γ)] has been recognized as a component of the “innate” immune response. The fact that blood levels of all these inflammatory cytokines have been found to be elevated in heart failure raises the question of whether increased iNOS expression is an adaptive or maladaptive response of the innate immune system (Fig. 3).

Molecular Pharmacology of NOS-Mediated Regulation of Cardiac Myocyte Contraction

To determine whether an L-arginine–NO pathway was functionally active in neonatal and adult rat heart cell preparations and whether it played a role in the response of these preparations to inotropic and chronotropic interventions, the effects of NOS inhibitors were first studied on the amplitude of contractile shortening and changes in beating frequency of cardiac myocytes from adult and neonatal rat hearts, respectively, in response to β -adrenergic and cholinergic agonists.

The Isolated Cardiomyocyte Model

The choice of single contracting cells as an experimental model for functional experiments offers some practical advantages: above all, compared to intact tissue or whole organ preparations, they provide a contracting entity where neurohumoral and/or paracrine influences are largely inconsequential. They also allow a direct correlation between biochemical and molecular observations in single cells and in roughly similar culture preparations. Because of the complexity of the mechanical determinants of muscle cell contraction, however, one should bear in mind that even though isolated cells represent an apparent simplification of intact muscle or organ preparations, they may in fact be downscal-

ing the problem from a megadimensional to merely a multidimensional ambiguity.

Among the most studied preparations, unattached cells (i.e., not physically attached to force transducers) are preferable because they exhibit less inhomogeneity in sarcomeric length variations. These unattached cells display a remarkable degree of regional sarcomeric uniformity both at rest and during active isotonic contraction. Still, the contractile behavior of unattached cells may be influenced by a number of variables (among these is the diastolic length that may influence the surface to volume ratio of the cells and perhaps the accessibility of ion exchange sites and actin/myosin cross-bridge cycling). In order to obtain maximal reproducibility, cells are routinely selected according to a number of criteria: stimulation threshold, shape, diastolic length, and absence of spontaneous contractions, as previously described (Berger *et al.*, 1994).

The edge-detection methods rely on some adhesion of the isolated cell to a stable surface. In these unattached myocytes, sarcomere length uniformity is well maintained during shortening. On the other hand, the exact load, both internal and external, against which the cells contract is not known. This emphasizes the need to carefully select the most straightforward, representative, and reproducible parameters with which to deduce the basis of changes in contractility in isolated cells, and to compare these with those observed in other models, for example, in multicellular preparations or intact tissue preparations.

A complete description of the mechanical component of the contractile process with which to relate the underlying biochemical processes would require measurements of force, stiffness, and shortening characteristics under a variety of perturbations. For technical reasons (mainly the difficulty of obtaining attachment of isolated myocytes to force transducers without perturbing sarcomeric homogeneity and sarcolemmal integrity), the establishment of the relation between active force development as a function of sarcomeric lengths remains an experimental challenge at the single cell level. The most extensive data, in this regard, have come from the analysis of shortening as an index of contractility.

Both the degree of shortening and the velocity of shortening (and relengthening) can be measured in a minimally loaded cell. The parallels that have been demonstrated between myocyte shortening responses and those of intact tissue confirm that the isolated myocyte is a useful model of cardiac tissue (e.g., Allen and Kentish, 1985). Since inotropic interventions may affect the maximum shortening and the rate of cell length change differently, a more complete assessment of contractility should include a description of both parameters. In the case of isoproterenol, the shortening and relaxation rates as well as the extent of cell shortening increase together, and previous studies have established the correlation between absolute changes in cell length and its first derivatives. Therefore, in most experiments with adult rat myocytes, only cell shortening amplitudes are presented. In the following sections we will first describe the paradigms originally proposed on the basis of single myocyte experi-

ments and correlate those with the results obtained in multicellular preparations or *in vivo* observations.

nNOS

Several lines of evidence indicate that nitric oxide produced endogenously by nerve terminals plays a role in the control of catecholamine release during electrical sympathetic nerve stimulation. This was confirmed in isolated perfused hearts (Schwarz *et al.*, 1995) but also *in vitro* in PC-12 cells (Kaye *et al.*, 1997) and in cocultures between peripheral cardiac neurons and cardiomyocytes from adult mammalian myocardium (Horackova *et al.*, 1995). In the latter experiments both exogenous NO release from *S*-nitroso-*N*-acetylpenicillamine (SNAP) and endogenous NO produced by cocultured intrinsic cardiac neurons acted to increase the spontaneous beating frequency of cocultured myocytes, whereas NO had no effect on monocultures of cardiomyocytes. These results are consistent with the interpretation that NO either increases the release or inhibits the reuptake of neuron-derived catecholamines at the presynaptic level. This interpretation was supported by independent experiments showing that *S*-nitrosothiols inhibit neuronal norepinephrine transport (Kaye *et al.*, 1997).

The physiological role of nNOS on cardiac function has been more directly examined *in vivo* in homozygous mice deficient for NOS1 (nNOS^{-/-} mice). Under baseline conditions, nNOS^{-/-} mice had a higher mean heart rate and lower heart rate variance than wild-type mice. Their chronotropic response to atropine was significantly blunted, suggesting a reduced baseline parasympathetic tone. However, the bradycardic response to a pressure challenge (i.e., phenylephrine injection after β -adrenergic blockade) in nNOS^{-/-} mice was similar to that observed in wild-type controls. The response to pressure challenge was strikingly more sensitive to pertussis toxin (PTX) pretreatment in nNOS^{-/-} mice compared to wild-type littermates, suggesting that the cardiac inhibitory G_i protein acts in parallel to neuronally derived NO to mediate autonomic slowing of heart rate in the mouse (Jumrussirikul *et al.*, 1998).

eNOS

MUSCARINIC CHOLINERGIC PATHWAY

The first evidence for a regulatory role of NOS constitutively expressed in cardiac myocytes on the muscarinic cholinergic pathway was provided by the study of the effect of pharmacological NO or NOS inhibitors on myocyte responsiveness to carbamylcholine. These experiments were initially performed in cultures of neonatal rat ventricular myocytes, in which changes in spontaneous beating rate (not contractile amplitude) were monitored. Despite theoretical caveats associated with the neonatal phenotype, the conclusions from these initial studies were later confirmed in isolated ventricular myocytes from adult rat hearts, intact hearts, and whole preparations. In addition, the ability of neonatal myocytes to undergo a (limited) number of cell

divisions in culture renders them more amenable to transfection for heterologous expression of plasmids encoding wild-type or mutated eNOS (e.g., in neonatal myocytes from eNOS^{-/-} mice, see later) or regulatory proteins, such as caveolin, thereby enabling a more in-depth analysis of the molecular regulation of eNOS-dependent muscarinic cholinergic coupling in these cells (see later).

Chronotropic Response of Neonatal Myocytes to Carbachol: Effect of NO/NOS Inhibitors We studied primary cultures of neonatal cardiac myocytes 3 days after isolation and plating, at which time their spontaneous rate of contraction usually has stabilized. Superfusion of this multicellular preparation with carbachol abruptly reduced the beating rate in these cells. The onset of the effect of carbachol was rapid, persisted through the duration of superfusion, and was completely reversible after drug washout. Repetitive applications of carbachol caused similar marked declines in beating rate. Similar experiments were then repeated in the presence of oxyhemoglobin or methylene blue, both of which abolished the negative chronotropic effect of carbachol. The effects of graded increases in carbachol concentration (100 nM to 3 mM) were also studied in the same preparation in the presence or absence of the NOS inhibitor N^G-methyl-L-arginine (L-NMMA) (1 mM). L-NMMA markedly attenuated the ability of carbachol to reduce the beating rate of neonatal myocytes in primary culture, an effect that was partially reversed after addition of an excess of L-arginine, the substrate for NOS.

These data indicate that cardiac myocytes respond functionally to products of an endogenous NO synthase. The number of nonmyocyte cells in neonatal rat ventricular myocyte primary cultures is relatively low (typically 10% or less), and thus the origin of the NO was presumed to be cardiac myocytes. Even though the interpretation of the inhibitory effect of methylene blue may be confounded by its well-known atropine-like effect, first described in the frog ventricle as early as 1926 (Cook, 1926), the consistent effect of several pharmacological NO/NOS inhibitors [i.e., oxyhemoglobin, L-NMMA] supported this conclusion.

The L-arginine analogs N^G-nitro-L-arginine (L-NNA) and L-NMMA attenuated the production of NO in a variety of tissues by inhibiting the transformation of L-arginine to L-citrulline plus NO by members of the NOS protein family (Moore *et al.*, 1990; Rees *et al.*, 1998). Although this inhibition could be reversed with an excess of the natural substrate, L-arginine, in most tissues, some analogs, including L-NMMA, may irreversibly inactivate the enzyme (Dwyer *et al.*, 1991). Thus, the incomplete restoration of the negative chronotropic effect of carbachol by L-arginine in the presence of L-NMMA may reflect the relatively greater affinity of the NOS antagonist arginine analogs in neonatal cardiac cells, as well as possible irreversible inactivation of the enzyme. Although it seemed plausible that cardiac muscle cells themselves produced NO in these experiments, this chemical signal could still have originated from other cell types within

these primary cultures and surrounding the myocytes in the ventricular wall.

Role of NO in Accentuated Antagonism: Muscarinic Cholinergic Modulation of L-Type Calcium Current and Cell Shortening of Adult Cardiomyocytes Prestimulated with Adrenergic Agonists More insights into the functional role of eNOS constitutively expressed in cardiac myocytes were gained in subsequent studies of the effect of various inhibitors of NO or eNOS on both calcium current and the contraction of single, isolated cardiac myocytes from adult rat hearts. In contrast to neonatal cell preparations, adult rat cardiomyocytes can be studied by combined video-motion analysis and electrophysiological measurements for both L-type calcium current intensity and unloaded cell shortening. The use of the nystatin-perforated patch-clamp technique further allows internal dialysis of single cells with drugs, such as L-NMMA, combined with external application of various agonists. A major difference with neonatal cells is that adult cardiac myocytes in the first 24 to 48 hours of isolation do not beat spontaneously but do contract in response to electrical stimulation. Subsequent superfusion with agonists such as isoproterenol, a nonselective β -adrenergic activator allows the observation of increases in cell shortening amplitude as a reflection of changes in inotropic state (see earlier). When a stable increase in cell shortening is obtained with isoproterenol, the subsequent application of carbachol attenuates the β -adrenergic inotropic response (whereas carbachol has little or no effect in the absence of isoproterenol prestimulation), an equivalent at the single cell level of classic pharmacological accentuated antagonism. In experiments with adult myocytes, this antagonistic effect of carbachol is used as a measurement of cellular responsiveness to muscarinic cholinergic stimulation.

In a series of experiments using these protocols in isolated ventricular myocytes from adult rat hearts, we showed that carbamylcholine attenuated the isoproterenol-stimulated increase in I_{Ca-L} and amplitude of unloaded cell shortening in paced ventricular myocytes. After extracellular perfusion or internal dialysis of the cell with the NO synthase inhibitor L-NMMA, the antagonistic effect of carbamylcholine on β -adrenergic stimulation of both I_{Ca-L} and the amplitude of unloaded cell shortening was totally abolished. A similar reversal of the effect of carbamylcholine on contractility was also observed after NO blockade with hemoglobin. Qualitatively and quantitatively similar results were obtained with sinoatrial and atrioventricular nodal cells from adult rabbit hearts (Han *et al.*, 1996).

Muscarinic Cholinergic Coupling Is Absent in Adult Cardiomyocytes from Mice with Targeted Disruption of eNOS

The conclusions based on the use of pharmacological inhibitors of NOS, as described earlier, were confirmed by a subsequent study of the accentuated antagonism exhibited by isolated ventricular myocytes from mice homozygous deficient for eNOS. The phenotype of these mice, originally developed and characterized by Paul Huang, Mark Fishman,

and their colleagues is characterized by the progressive development of hypertension, mostly as a result of the loss of endothelial production of NO (Huang *et al.*, 1995).

The contractile response to maximal stimulation with Iso was unchanged in these eNOS $-/-$ myocytes, as was maximal L-type calcium current. However, the antagonistic effect of carbachol on the adrenergic response, which was clearly observed in myocytes from wild-type animals (as described previously) was lost in myocytes from eNOS $-/-$ mice (Han *et al.*, 1998b). Importantly, this was paralleled in the same cells by the inability of carbachol to increase intracellular cGMP levels, whereas in myocytes from wild-type (eNOS $+/+$) animals, cGMP levels clearly responded to carbachol stimulation and were sensitive to NOS inhibitors.

These results contrast with those from a subsequent study by Vandecasteele *et al.* (1999) who found no alteration of the muscarinic cholinergic response in cardiac cell muscle preparations from eNOS $-/-$ mice. However, in our opinion, their contention that eNOS does not mediate muscarinic regulation of the heart is weakened by several methodological shortcomings. Foremost is the fact that their eNOS $-/-$ mice were not matched with the appropriate controls: (1) homozygous founder mice were not backcrossed into their appropriate strains to obtain homogenous genetic backgrounds between eNOS $-/-$ and control eNOS $+/+$ mice, as is advisable in such comparative studies; (2) the eNOS $-/-$ mice used in the report by Vandecasteele *et al.* (1999) were studied between 3 and 6 months of age, when the chronic hypertension characteristic of this genetic model had resulted in a significant myocardial hypertrophy, a phenotype not independently accounted for in their comparison with normal controls (see comments by Hare and Stamler, 1999); (3) in their multicellular (papillary muscle and particularly, atrial) preparations, the persistence of the response to muscarinic cholinergic agonists in tissues from eNOS $-/-$ mice may be explained by the activation of $I_{K(Ach)}$ which is known to be present in atrial and ventricular cells (Han *et al.*, 1998b) and can be upregulated in response to hypertrophic stimuli (Guo *et al.*, 1997); (4) such confounding effects of K^+ currents should have been controlled by Cs^+ -containing intracellular and extracellular solutions in the experiments with single ventricular myocytes; however, the experiments described by Vandecasteele *et al.* (1999) were all performed at room temperature (19°–23°C), and the authors do not provide independent evidence that eNOS (in control myocytes) is active at such low temperatures, thereby preventing any valid comparison; and (5) there are precedents for misleading conclusions based on experiments designed to measure enzymatic activity when performed at temperatures well below 37°C (e.g., see the opposite conclusions regarding the functionality of a cyclic ADP ribose(cADPR) pathway in cardiomyocytes reached by Guo *et al.*, 1996 and Iino *et al.*, 1997, depending on the temperatures used to assay the activity of this pathway).

In contrast, in the study by Han *et al.* (1998b), eNOS $-/-$ mice were appropriately backcrossed into their CR7/B6 and 129SvEv backgrounds, and studied at a younger age when significant cardiac hypertrophy had not yet occurred.

Electrophysiological experiments were also performed at 32.5°C. Whether these technical differences account for all of the discrepancy between these two studies will await further experimental confirmation.

Caveolar Targeting of the Muscarinic Cholinergic/eNOS Pathway

SUBCELLULAR LOCALIZATION OF eNOS The experiments described above suggest that the generation of nitric oxide is an obligate intermediate step in the signal transduction cascade involved in the muscarinic cholinergic (mAChR)-mediated inhibitory responses in the heart, at least in rodents. The colocalization within caveolae of eNOS and calmodulin with proteins known to regulate Ca^{2+} homeostasis, including a Ca^{2+} -ATPase and IP_3 receptor-like proteins, as well as with heterotrimeric G proteins (for references, see Couet *et al.*, 1997; Okamoto *et al.*, 1998), suggest that these plasmalemmal microdomains could constitute the platform for the recruitment and regulation of the signaling proteins involved in the NO-mediated muscarinic cholinergic pathway in heart muscle. Therefore, it was hypothesized that the dynamic targeting of agonist-stimulated muscarinic cholinergic receptors to caveolae in cardiac myocytes could facilitate the activation of eNOS.

As mentioned earlier, several studies have shown that, of the five mAChR subtypes identified to date, only the m1 and m2 subtypes are expressed in adult mammalian cardiac tissues (Gallo *et al.*, 1993; Sharma *et al.*, 1996). According to these reports, the m2 mAChR, which is expressed in the heart at a higher level than the m1 mAChR, triggers the inhibitory response, while m1 receptor activation, when stimulated by higher concentrations of agonist, elicits a compensatory excitatory effect on heart function. Therefore, distinct downstream signaling cascades must be involved following m1 and m2 mAChR activation. Both m1 and m2 receptor subtypes have also been reported to undergo translocation into specific subcompartments derived from plasma membrane (Harden *et al.*, 1985; Svoboda and Milligan, 1994; Goldman *et al.*, 1996), a characteristic of many G-protein-coupled receptors (GPR) following agonist binding. To date, two major pathways for GPR clustering and sequestration, which involve plasma membrane modifications that lead to the formation of either clathrin-coated or noncoated vesicles, have been reported. Whereas the human muscarinic cholinergic receptor Hm1 has been shown to internalize via clathrin-coated vesicles (Tolbert and Lamah, 1996), mAChRs have also been shown to be internalized through non-clathrin-coated vesicles in human fibroblasts, although the identity of these vesicular structures has not been defined (Raposo *et al.*, 1987).

A series of experiments was therefore designed to explore the hypothesis that m2 mAChRs are targeted to plasmalemmal caveolae on agonist stimulation in adult rat ventricular myocytes. Caveolin-enriched membranes have been historically isolated on the basis of their insolubility in nonionic detergents (such as Triton) due to their specialized lipid composition (Sargiacomo *et al.*, 1993). However, it has been

reported that the inclusion of these detergents can result in the loss of proteins normally associated with caveolae (Smart *et al.*, 1995; Song *et al.*, 1996). Therefore, for isolating caveolae from cardiac myocytes, we have optimized a detergent-free purification method based on the resistance to extraction of caveolin complexes by sodium carbonate and on the fine disruption of cellular membrane by sonication, and followed by an overnight isopycnic centrifugation on sucrose gradient, as described for cardiac myocyte membranes (Feron *et al.*, 1997).

In these experiments, the majority of caveolin-3 and eNOS in ventricular myocyte preparations appeared in low density fractions which correspond to the 5–15% sucrose equilibrium densities (Feron *et al.*, 1997). This copurification of eNOS and caveolin-3 was in agreement with previous data on the coimmunoprecipitation of these two proteins from cardiac myocyte lysates (Feron *et al.*, 1996). As indicated by the pattern of distribution of various membrane markers across the gradient, the bulk of cellular protein that equilibrates at the high sucrose density corresponds to Golgi and sarcolemmal membranes (Feron *et al.*, 1997). Along with the immunohistochemical data mentioned above, these coimmunoprecipitation experiments also provided additional evidence for an association of eNOS with caveolin-3 in cardiac myocytes.

M2 AChR IN MYOCYTES TRANSLOCATE TO CAVEOLAE ON AGONIST STIMULATION Interestingly, when exploring the effects of carbachol, a muscarinic cholinergic agonist, on the distribution of mAChR using the protocol described above, changes in receptor subcellular localization were observed (Feron *et al.*, 1997). Using the muscarinic cholinergic radioligand [^3H]QNB as a marker, mAChRs were almost exclusively found in high-density fractions issued from untreated myocyte lysates. In contrast, following carbachol treatment, one-third of the [^3H]QNB binding was recovered in low-density fractions, which corresponded to the caveolin-enriched membranes. The rest of the [^3H]QNB binding remained concentrated in a heavy membrane fraction and thus likely represented binding to noncaveolar sarcolemmal muscarinic receptors. Importantly, antibodies directed against the m2 mAChR and caveolin-3 were used to immunoprecipitate caveolar membranes and confirmed the dynamic targeting of muscarinic receptors to caveolae in cardiac myocytes.

Taken together, these data establish that the m2 mAChR is targeted to plasmalemmal caveolae of cardiac myocytes following agonist binding. The dynamic targeting of the m2 mAChR to caveolae has important implications for muscarinic receptor biology as well as for the regulation of eNOS activation. The copurification and coimmunoprecipitation of caveolin, eNOS, and the agonist-stimulated m2 mAChR in isopycnic centrifugation fractions (Feron *et al.*, 1996, 1997), which together represent less than 5% of total cellular protein, indicate that caveolae are a common structural platform for these proteins. The caveolar compartmentation described here for the muscarinic cholinergic pathway may serve as a

paradigm for other G protein receptor-mediated signaling cascades that are targeted to caveolae.

While numerous studies present the sequestration of G-protein-coupled receptors after agonist stimulation as a key event for initiating a process of desensitization (see Lefkowitz, 1998), our data support the hypothesis that, following stimulation by agonist, cardiac m2 mAChR translocation to caveolae may also be required to initiate specific downstream signaling cascades. Interestingly, several studies have shown that internalization of the m2 and m4 mAChR is mediated by mechanisms distinct from the phosphorylation by the G-protein-coupled receptor kinase (GRK) family known to lead to receptor desensitization (Pals-Rylaarsdam *et al.*, 1995; Bogatkevitch *et al.*, 1996). The translocation of muscarinic receptors within caveolae would allow their interaction with heterotrimeric G-protein complexes known to be concentrated within these plasmalemmal microdomains and lead, after recruitment of cofactors and intermediate effector proteins, to the activation of eNOS, a resident caveolar protein in cardiac myocytes.

POSTTRANSLATIONAL MODIFICATIONS OF eNOS AFFECT ITS CAVEOLAR TARGETING Quantitative changes in NOS expression have been causally associated with cardiovascular disease states (Loscalzo and Welch, 1995). Likewise, the abrogation of NOS expression by targeted gene inactivation, or, conversely the enhancement of NOS pathways by gene overexpression, have permitted insights to be gained by generating quantitative changes in NOS abundance (Moncada and Higgs, 1995). However, it seems equally likely that qualitative changes in the NOS pathway may underlie many important aspects of NO physiology and pathophysiology. At least some of these qualitative changes may be affected by alterations in the posttranslational modifications of the enzyme, subcellular targeting, or protein-protein interactions. eNOS in endothelial cells and in cardiac myocytes undergoes cotranslational myristoylation and posttranslational palmitoylation. Myristoylation, in particular, is necessary for eNOS targeting to plasmalemmal caveolae (Michel and Feron, 1997). Moreover, as mentioned earlier, eNOS appears to be quantitatively associated with caveolins (caveolin-1 in endothelial cells and caveolin-3 in cardiac myocytes) through a stable interaction taking place at consensus sequences present in both partners which appears to contribute to downregulation of enzyme activity (Michel *et al.*, 1997). In endothelial cells, following agonist stimulation, Ca^{2+} -bound calmodulin is known to activate eNOS by disrupting the heteromeric complex formed between eNOS and caveolin (Feron *et al.*, 1998a,b). A regulatory cycle is then initiated wherein activated, caveolin-free eNOS, translocates from caveolae, and is followed by the enzyme reassociation with caveolin when Ca^{2+} returns to basal levels (a similar regulatory cycle is presumed to occur in cardiac myocytes) (Michel and Feron, 1997; Feron *et al.*, 1998b; Feron, 1999).

The targeting of eNOS in plasmalemmal caveolae probably facilitates paracrine signaling by NO, a pathway most clearly delineated in endothelial cells within the vascular

wall. Furthermore, since an increase in shear stress appears as one of the most effective activators of NO production in endothelial cells, it seems logical to expect that at least for the flow responsive pool of eNOS, it would be more efficient for the enzyme to reside at the endothelial cell surface (Rizzo *et al.*, 1998). In cardiac myocytes, eNOS is also located within plasmalemmal caveolae (Feron *et al.*, 1996), but to date, the NO generated has only been shown to act in an autocrine fashion by modulating myocyte responsiveness to neurohumoral or mechanical stimuli. NO produced by myocytes has various endogenous targets (see later sections), and the location of eNOS within plasmalemmal caveolae of these cells is probably unrelated to a requirement for extracellular diffusion of NO, as documented for the endothelial cells. Instead, the functional importance of the subcellular location of eNOS in myocyte plasmalemmal caveolae appears to be the close proximity with regulatory proteins such as caveolin and calmodulin as well as with receptors and G protein-dependent signaling cascades.

MOLECULAR DETERMINANTS OF MYOCYTE eNOS TARGETING TO CAVEOLAE eNOS is unique among the NOS isoforms because it is acylated by the fatty acids myristate and palmitate (Sase and Michel, 1997). Whereas myristoylation is an essentially irreversible protein modification, thiopalmitoylation is a reversible posttranslational modification which may undergo dynamic regulation (Sase and Michel, 1997). Depalmitoylation was indeed proposed to occur following agonist stimulation, thereby promoting the enzyme translocation (Sase and Michel, 1997), and inversely, palmitoylation was shown to play an obligatory role for the retargeting of translocated eNOS to caveolae (Feron *et al.*, 1998b). Although it has been proposed that agonist-induced translocation of eNOS is part of a desensitization process, the use of acylation-deficient mutants was restricted to conventional transfectable cells, and this presented inherent limitations in the study of the effects of eNOS mistargeting on signal transduction in cardiac myocytes. On the other hand, the confounding effect of endogenous eNOS expressed in specialized cells, such as cardiac myocytes, hampered the interpretation of the data resulting from the expression of acylation-deficient eNOS mutants in these noncontractable cells.

We were able to overcome this experimental limitation, however, by the isolation of ventricular myocytes from neonatal mice with targeted disruption of eNOS (i.e., eNOS $^{-/-}$, as described earlier). Myocytes from eNOS $^{-/-}$ mice were subsequently transfected with cDNA constructs encoding for either wild-type eNOS or a myristoylation-deficient (myr $^{-}$) eNOS mutant. Inactivation of the eNOS myristoylation site (glycine₂ mutated to alanine) not only blocks myristoylation but also prevents subsequent enzyme palmitoylation yielding an acylation-deficient enzyme. Accordingly, in transfected neonatal eNOS $^{-/-}$ mice myocytes, expression of the acylation-deficient myr $^{-}$ eNOS mutant appeared restricted to the cell cytosol, and the mutant enzyme could not be coimmunoprecipitated by caveolin antibodies (Feron *et al.*, 1998c). In contrast, the distribution of recombinant

wild-type (WT) eNOS expressed in transfected neonatal eNOS^{-/-} mice myocytes was similar to that of native myocyte eNOS, and was found almost exclusively located in the particulate fraction associated with caveolin. Therefore, this approach provided an experimental model for eNOS signaling within cardiac myocytes with eNOS subcellular localization restricted to either caveolae or the cytosol. This permitted us to specifically address the role of eNOS caveolar targeting and the functionality of its coupling to muscarinic cholinergic stimulation.

Importantly, the normal response of myocytes to autonomic nervous system agonists could be rescued in eNOS^{-/-} myocytes by transfection with a wild-type but not the acylation deficient myr⁻ mutant eNOS (Feron *et al.*, 1998c). Indeed, in eNOS^{-/-} myocytes expressing recombinant WT eNOS, as with myocytes from backcrossed wild-type animals, the muscarinic cholinergic agonist carbachol elicited a strong negative chronotropic response and markedly activated cGMP production. In contrast, in myr⁻ mutant eNOS transfected myocytes, the response to muscarinic cholinergic stimulation was absent as a consequence of the single amino acid substitution preventing eNOS acylation and targeting to caveolae. Importantly, the calcium ionophore A23187, which increases intracellular Ca²⁺ in a receptor-independent fashion, increased cellular cGMP levels in myocytes expressing the myr⁻ eNOS mutant to a level equivalent to that seen with the WT enzyme. Since the absolute capacity to generate NO was not different for both wild-type and mutant eNOS constructs transfected into eNOS^{-/-} myocytes, it can be postulated that the myr⁻ eNOS mutant is uncoupled from the muscarinic receptor because of the aberrant subcellular localization of the mutant and failure to target to caveolae. This result clearly established the key role of eNOS location in plasmalemmal caveolae for its activation and regulation of cardiac myocyte function.

THE CAVEOLIN-3–eNOS INHIBITORY INTERACTION IN CARDIAC MYOCYTES As mentioned above, the caveolin isoform expressed in myocytes, caveolin-3, exhibits only an ~60% amino acid identity with the caveolin-1 isoform expressed in endothelium, the C-terminal juxtamembranous region of 20 amino acids within both caveolin isoforms that have been shown to specifically interact with the α subunit of G proteins and modulate their GTPase activity (Song *et al.*, 1996; Tang *et al.*, 1996). The functionality of this caveolin-3 scaffolding domain, however, has only been more recently resolved by the identification of this modular protein domain as an endogenous inhibitor of eNOS activity in cardiac myocytes (Feron *et al.*, 1998c).

To address the specificity of the interaction between eNOS and caveolin-3, an approach that allows specific peptides to enter cultured myocytes by reversible cell permeabilization was used. Neonatal rat myocytes that endogenously express eNOS and caveolin-3 were permeabilized to introduce synthetic oligopeptides corresponding to the scaffolding domain of caveolin-3, using a method developed by Morgan and Morgan (1982) for loading aequorin into vas-

cular smooth muscle cells. Reversible permeabilization of myocytes was obtained by their exposure to an ice-cold solution containing a Ca²⁺ chelator and the peptide, followed by the progressive rewarming of the medium bathing the myocytes and the restoration of physiological calcium concentration. This method does not require the use of detergents such as saponin but still allows the introduction of control polydextran (5–100 kDa) into the cells. Importantly, neonatal myocytes spontaneously began beating following the permeabilization protocol, thus allowing us to study the functional consequences of the modulation of the caveolin-3–eNOS interaction on the beating rate. The paradigm of muscarinic cholinergic NO-mediated regulation of heart rate has been established in this model of cultured neonatal myocytes (see earlier), offering a model system to study the posttranslational modification of an eNOS-mediated pathway in cardiac myocytes. Using neonatal rat ventricular myocytes, which beat spontaneously beginning 3 days after isolation, we performed measurements of beating rate which was determined on a temperature-controlled chamber on the stage of a microscope connected to a video-motion analyzer.

Two different peptides were used in these experiments: peptides containing the caveolin scaffolding domain corresponding to residues 55–74 of the rat caveolin-3 sequence (termed Cav-3); and a scrambled peptide (termed Cav-3X), wherein residues were exchanged pairwise at eight highly conserved positions within the 20 amino acid sequence of the Cav-3 peptide. The use of this conservatively designed peptide as control, which shares 100% identical amino acid composition and 60% amino acid sequence identity with the Cav-3 peptide, helped to ascertain the specificity of the effects seen with the Cav-3 peptide.

The permeabilization protocol did not significantly alter the basal beating rate which amounted to 70 ± 3 and 72 ± 4 min⁻¹ ($n = 5$), before and after the peptide loading. When sham-permeabilized myocytes were exposed to 1 μ M carbachol, myocyte spontaneous contractions were completely abrogated; several minutes of wash out were required to restore the initial beating rate. In contrast, in neonatal myocytes loaded with the Cav-3 peptide, carbachol did not induce any change in beating rate. The specificity of this effect was demonstrated by using myocytes loaded with the control peptide Cav-3X. This scrambled control peptide did not alter the inhibitory effect of carbachol on the rate of myocyte contraction. Furthermore, cGMP determinations performed on parallel myocyte cultures revealed that the Cav-3 peptide inhibited the carbachol-evoked increase in cGMP levels to about the same extent as observed with the NOS inhibitor L-NNA applied on sham-permeabilized myocytes. Importantly, the Cav-3X peptide failed to reverse the fourfold increase in cGMP observed in control native myocytes.

These experiments validate the hypothesis according to which the compartmentation of eNOS within caveolae is intimately linked to the regulation of its activity by the interaction with caveolin. The close control of eNOS activity by caveolin is probably required to maintain a low basal production of NO and to protect the cell from undesired, po-

tentially cytotoxic, or nonphysiological bursts of NO in response to subtle increases in intracellular calcium. Enzyme kinetic analyses revealed that caveolin serves as a competitive inhibitor of calmodulin-dependent eNOS activation (Michel *et al.*, 1997). The calmodulin binding consensus sequence is located at the N terminus of the eNOS reductase domain, and calmodulin binding to this site activates NO synthesis by enabling the reductase domain to transfer electrons to the oxygenase domain (Ghosh *et al.*, 1998). Calmodulin is therefore likely to rescue the caveolin-inhibited eNOS by antagonizing the blockade (or slowing) of electron transfer due to the binding of caveolin to either of the domain of the enzyme. Therefore, the close control of enzyme activity may be particularly important for eNOS in caveolae, where calmodulin is enriched (Shaul *et al.*, 1996), potentially leading to undesired enzyme activation if the interaction of caveolin with eNOS were not keeping the system in check.

eNOS-Mediated Muscarinic Cholinergic Coupling in Other Mammalian Species Negative studies from others have emphasized that coupling of muscarinic cholinergic GPRs to NO production may not be operative in all animals species or even in all regions of the heart. The pathway seems to be functionally absent in frog atrial myocytes (Méry *et al.*, 1996), ventricular myocytes from adult guinea pigs (Stein *et al.*, 1993), or in papillary muscle from failing or nonfailing human hearts (Kilter *et al.*, 1995). In a study on the regulation of L-type calcium current of human atrial myocytes that is sensitive to application of exogenous NO donors, Vandecasteele and colleagues again found no effect of NO synthase inhibitors on the muscarinic cholinergic regulation of either baseline or adrenergically stimulated calcium current (Vandecasteele *et al.*, 1998). As noted earlier, in addition to other explanations for these discrepancies with our data, there was no assessment of NO production from these preparations with an independent technique in a particular experimental condition used (e.g., at temperatures lower than 37°C).

On the other hand, the involvement of endogenous NO in the parasympathetic regulation of heart function has been confirmed in a number of tissue preparations and *in vivo* models. In the anesthetized ferret adrenergically blocked with propranolol, NO synthase inhibitors significantly reduced the bradycardia induced by vagal stimulation, an effect that could be reversed by infusion of an excess of L-arginine (Conlon *et al.*, 1996). Similarly, in the anesthetized dog, infusion of L-NMMA into the sinus and atrioventricular nodal arteries attenuated the negative chronotropic and dromotropic responses to vagal nerve stimulation in the absence or presence of adrenergic activation (Elvan *et al.*, 1997). NOS inhibition, however, may not always affect the direct cholinergic actions of infused acetylcholine. In a series of experiments in anesthetized rabbits and in isolated guinea pig atria with preserved vagal innervation, Sears and colleagues outlined the existence of regulatory roles of exogenous or endogenous NO at various levels of cholinergic

neurotransmission (Sears *et al.*, 1998, 1999). In isolated guinea pig atria, inhibition of nitric oxide synthase did not affect the maximal response rate to vagal nerve stimulation in adrenergically pretreated preparations, but significantly slowed down the time course of the vagal negative chronotropic effect. On the basis of the subsequent observation of an acceleration of the rate response to vagal stimulation in the presence of inhibitors of the hyperpolarization-activated current, or I_h , which is known to be stimulated by NO (Musialek *et al.*, 1997), they proposed that the modulatory role of endogenous NO on the vagal response may integrate both a potentiating effect, presumably mediated through inhibition of I_{Ca-L} , and an antagonistic effect activating I_h , both of which are superimposed on the direct activation by acetylcholine of $I_{K(Ach)}$, at least at the atrial level. Moreover, these authors observed that application of exogenous NO donors or 8-bromo-cyclic GMP potentiated the chronotropic effect of vagal nerve stimulation but not of directly applied acetylcholine, thereby implicating an additional role of NO at the presynaptic level, a conclusion in agreement with previous results in the anesthetized dog (Elvan *et al.*, 1997). The existence of functionally opposed effects of NO on the control of heart rate due to interaction with multiple currents (i.e., I_{Ca-L} , I_h , but not $I_{K(Ach)}$) in the atria probably explains the contradictory results provided by different laboratories, depending on the preparation and protocol used (i.e., using intact vagal nerve stimulation versus direct application of acetylcholine, in the presence or absence of initial adrenergic stimulation), and the species employed (which may affect the relative contribution of each current to the control of heart rate). In humans, we observed a partial abrogation of the accentuated antagonism by NOS inhibitors in electrically paced atrial strips exposed to acetylcholine after submaximal stimulation with isoproterenol (Gauthier *et al.*, 1998b).

In this regard, the contribution of eNOS to accentuated antagonism relative to other intracellular pathways coupled to muscarinic cholinergic receptors may be more identifiable at the ventricular level, given the absence of expression and/or significant functional role of $I_{K(Ach)}$ and I_r in ventricular cells. As for other muscarinic cholinergic responses, $G_{i/o}$ proteins appear to be critical in the coupling of the NO-mediated accentuated antagonism. Pretreatment of rats with pertussis toxin not only abolished the muscarinic cholinergic accentuated antagonism, which was shown to be NO-mediated, but also controlled the abundance of eNOS proteins in the isolated hearts from the same animals (Hare *et al.*, 1998a).

Finally, endogenous nitric oxide was also shown to mediate the indirect effects of adenosine on calcium current in rabbit heart pacemaker cells (Shimoni *et al.*, 1996), thereby recapitulating the paradigm proposed for muscarinic cholinergic coupling in the heart.

β-ADRENERGIC PATHWAY

The concept of a tight regulation of eNOS activation following muscarinic cholinergic receptor stimulation could theoretically be extended to other GPR associated with increases in intracellular calcium, the key activator of the

enzyme. As such, β -adrenoreceptors are well known to increase cytosolic calcium through stimulation of calcium influx through L-type calcium channels. According to the paradigms developed earlier, any subsequent activation of eNOS would exert a negative inotropic influence opposing the classic positive inotropism of the adrenergic pathway, thereby acting as a negative feedback mechanism.

Effects of NOS Inhibitors on the Positive Inotropic Effect of Isoproterenol in Adult Ventricular Myocytes Experiments were designed therefore to examine whether an NO-mediated signaling system could regulate the contractile (inotropic) response of ventricular myocytes to the β -adrenergic agonist isoproterenol. Adult rat ventricular myocytes were exposed to 2 nM isoproterenol, a concentration determined to yield about a half-maximal increase in contractile amplitude, in the presence or absence of NOS inhibitors. L-NMMA had no effect on baseline contractile function, but significantly potentiated the inotropic response to isoproterenol compared with that in myocytes superfused with control, L-arginine-containing medium.

The increase in the contractile response of adult rat ventricular myocytes to isoproterenol by NOS inhibitors suggested the existence of a countervailing, negatively inotropic, NO-mediated mechanism limiting the effect of β -adrenergic stimulation in adult myocytes. In this regard, the role of NO in cardiac muscle would be analogous to the control of the vascular tone by endothelium-derived NO (Egleme *et al.*, 1984; Furchgott and Zawadzki, 1980; Martin *et al.*, 1986; Godfraind *et al.*, 1985).

eNOS Is Activated by β_3 -Adrenergic Stimulation in Cardiac Muscle The activation by catecholamines of negative inotropic effects can be rationalized in terms of the concurrent activation of a family of adrenergic receptors coupled to different intracellular pathways. In 1996, Gauthier *et al.* had described the functional expression of adrenoreceptors of the β_3 subtype in human ventricular muscle. β_3 -adrenoceptors had been extensively studied for their role in mediating catecholamine-induced lipolysis in fat tissue, and had so far been considered to exclusively play a metabolic role. Their expression in cardiac tissue was demonstrated at the mRNA level, and confirmed more recently at the protein level (S. Moniotte and J. L. Balligand, unpublished results 2000), with significant levels of expression in cardiomyocytes. In contrast with β_1 - or β_2 -receptors, activation of β_3 -adrenoceptors with isoform-selective agonists (e.g., BRL37344) or isoproterenol in the presence of full β_1 and β_2 blockade produced a striking negative inotropic effect, as measured by peak tension development of human ventricular biopsies in organ baths (Gauthier *et al.*, 1996). This effect was also completely abrogated by pretreatment with pertussis toxin, suggesting coupling through G proteins of the α_{i-o} subtypes.

Subsequent experiments demonstrated that the β_3 negative inotropic effect was mediated through activation of eNOS in human ventricular tissue (Gauthier *et al.*, 1998a), thereby lending support to our interpretation of the activation

of countervailing inotropic pathways through different adrenoreceptors. As mentioned earlier, this paradigm somewhat recapitulates in the heart a similar coactivation of contracting and relaxing effects by catecholamines in the vasculature, where the resulting tone is controlled by a balance between direct vasoconstriction of smooth muscle and production of endothelium-derived relaxing factors, including NO. In the heart, the presence of both pathways (i.e., positively inotropic and NO-dependent negatively inotropic pathways) within each cardiac myocyte yields a similar negative feedback mechanism but in an autocrine fashion. Predictably, qualitative or quantitative alterations in either limb would alter the responsiveness to adrenergic stimulation and potentially contribute to the development of myocardial dysfunction, as reviewed later.

eNOS and Adrenergic Responsiveness in Other Cardiac Preparations Subsequent studies have emphasized that the functional consequence of endogenous NO production by eNOS on cardiac contraction is complex, with effects on peak contraction, duration of contraction, and onset of relaxation, the direction and magnitude of which vary according to the preparation used and the species considered. In addition, some confusion has arisen when results obtained with endogenous NOS inhibitors were directly compared with those of exogenous NO donor drugs. Experiments with the latter have identified a potentiation or a downregulation of the contractile response to β -adrenergic agonists in isolated hearts or cardiomyocytes, depending mainly on the concentration of the NO donor applied. Most studies evaluating the contractile effect of NO endogenously produced by eNOS do not identify an enhancement but rather an attenuation of the inotropic effect of catecholamines on heart muscle, as shown in our initial experiments detailed earlier. A similar observation was later reproduced in rat isolated atria (Sterin-Borda *et al.*, 1998) and atrial strips from human hearts (Gauthier *et al.*, 1998b). Furthermore, in rat atrial and ventricular myocytes, as well as in human ventricular tissue, exposure to isoproterenol induced an increase in intracellular cyclic GMP that was significantly reduced with NOS inhibitors (Gauthier *et al.*, 1998a; Sterin-Borda *et al.*, 1998; Joe *et al.*, 1998).

Several subsequent studies have since validated this paradigm in different animal preparations *in vivo*, where endogenous NO production blunts the positive inotropic effect of either infused catecholamines (Keaney *et al.*, 1996) or submaximal electrical stimulation of the left stellate ganglia in dogs (Takita *et al.*, 1998). In the latter study, intracoronary infusion of the NOS inhibitor, L-nitroarginine methyl ester (L-NAME), also significantly increased plasma norepinephrine concentration. The concept of eNOS-mediated attenuation of catecholamine effects received further confirmation from experiments in myocytes isolated from eNOS $^{-/-}$ myocytes, which exhibited an enhanced contractile responsiveness to positive inotropic agents in comparison to wild-type controls. This finding, independently obtained by two different groups (Gyurko *et al.*, 1997; Godecke *et al.*, 1998) was

not confirmed in a third study using isolated ventricular myocytes from these eNOS $^{-/-}$ mice, where the absence of potentiation of the effect of isoproterenol could be accounted for by the use of maximal stimulating concentrations of isoproterenol (1 μ M and greater) (Han *et al.*, 1998a).

LUSITROPIC EFFECTS OF ENOS

In the absence of pretreatment with catecholamines, stimulation of endocardial endothelial cells of ferret papillary muscles with substance P was shown to produce a shortening of the duration of contraction by inducing earlier onset of relaxation, with little effect on the peak force of contraction (Smith *et al.*, 1991). Qualitatively similar results were later obtained with bradykinin or substance P in isolated ejecting guinea pig hearts (Grocott-Mason *et al.*, 1994). In ventricular biopsy samples of human transplanted hearts which contain a mixture of endocardial and microvascular endothelial cells, and cardiac myocytes, activation of eNOS through β_3 -adrenoceptor stimulation did not significantly alter the shape of electrically stimulated contractions [i.e., the shortening of the time to half-relaxation was mainly the result of a marked decrease in developed peak tension, without a significant change in diastolic relaxation (Gauthier *et al.*, 1998a)]. However, a study of the contractile performance of human transplanted hearts *in vivo* led to the observation that intracoronary administration of substance P reproduced the pattern of earlier onset of relaxation with a marginal decrease in peak systolic performance (Bartunek *et al.*, 1997), as has been previously identified in animal papillary muscle or isolated ejecting hearts. In addition, the interaction between β -adrenergic stimulation and the paracrine effects of substance P was examined by monitoring systolic and diastolic parameters in response to substance P infusion during the continuous infusion of dobutamine. Even though the results were mainly interpreted as an accentuation of the lusitropic effect of paracrine NO compared to that obtained with substance P alone, this study also showed a significant attenuation of the positive inotropic effect of dobutamine by NO that recapitulates the paradigm of the counterregulatory effect of eNOS activation on the response to catecholamines as detailed in the previous sections.

The mechanism underlying the potentiation of the lusitropic effect of substance P in the context of prestimulation with a β -adrenergic agonist remains elusive. It has been proposed to result from synergistic actions of NO-derived cyclic GMP and β -adrenergic-dependent activation of protein kinase A to desensitize contractile myofilaments to calcium. This interpretation appears to contradict the demonstration in isolated rat cardiomyocytes that the cyclic GMP and protein kinase G-mediated desensitization of cardiac myofilaments to calcium is abolished on concurrent stimulation with the β -adrenergic agonist isoproterenol (Shah *et al.*, 1994).

EFFECTS OF EXOGENOUS NO DONORS ON β -ADRENERGIC RESPONSIVENESS

Despite important biochemical differences between NO generated by exogenous NO donors or NO endogenously

produced by nitric oxide synthase targeted to specific subcellular compartments, the use of nitrovasodilators or similar drugs has been valuable in understanding the potential intracellular mechanisms for the NO regulation of cardiac function. As previously observed with the regulation of L-type calcium current in isolated myocytes (Ono and Trautwein, 1991; Kirstein *et al.*, 1995), exogenous NO donors or cyclic GMP analogs exerted a biphasic effect on β -adrenergically induced positive inotropic effects depending on the concentration of the NO donor and the resulting increase in intracellular cyclic GMP (Fig. 4). This was shown both in isolated ventricular myocytes and papillary muscles from rats (Kojda *et al.*, 1996), open-chest dog hearts (Preckel *et al.*, 1997), and isolated feline papillary muscles (Mohan *et al.*, 1996). In the study by Mohan *et al.* (1996), a biphasic effect on developed tension was observed with either 8-bromo-cyclic GMP or treatment with zaprinast, an inhibitor of phosphodiesterase type V that increases endogenous cyclic GMP levels. Low concentrations of NO donor agents (and a resulting small increase in intracellular cGMP levels) increased developed tension, whereas higher concentrations resulted in a negative inotropic effect. Interestingly, the transition from positive to negative inotropic effect was shifted to lower concentrations of NO donor agents or zapri-

Figure 4 Intracellular pathways for the action of NO on excitation-contraction coupling.

nast when the muscles had been prestimulated with either muscarinic cholinergic agonists or with the β -adrenergic agonist isoproterenol. Even though the precise mechanism of the sensitization by previous β -adrenergic stimulation to the negative inotropic effect of cyclic GMP remained undetermined from these experiments, it is tempting to speculate that it may be related to the activation by isoproterenol of an endogenous nitric oxide synthase to further increase endogenous cyclic GMP, as observed in rat ventricular myocytes (Joe *et al.*, 1998) and human ventricular biopsies (Gauthier *et al.*, 1998a). The concentration-dependent shift from a positive to a negative inotropic effect of cyclic GMP elevation in the presence of β -adrenergic stimulation has not been observed in all species. For example, in a study on isolated ejecting guinea pig hearts, Prendergast and colleagues exclusively observed positive inotropic influences of either exogenous sodium nitroprusside or intracoronary substance P with β -adrenergic stimulation with dobutamine (Prendergast *et al.*, 1998). This positive inotropic influence was manifested only by a change in the decay of the peak developed pressure in response to long-term infusion of dobutamine, with no change in peak response to the catecholamine. Surprisingly, contrary to the previously mentioned observations in transplanted patients using similar protocols (Bartunek *et al.*, 1997), substance P had no significant effect on the lusitropic effect of dobutamine, emphasizing the need for caution when extrapolating functional results across species.

Regulation by iNOS

There is extensive evidence for the expression of iNOS protein in the multiple cell types comprising cardiac muscle, including in humans, in a variety of pathological conditions such as sepsis, transplant rejection, and in certain cases, heart failure. In these circumstances, the physiological/pathological role of NO extends beyond the fine tuning of cardiac contractile response to autonomic stimulation, as is the case for eNOS. NO produced by the "high output" iNOS enzyme has been implicated in many aspects of cardiomyocyte biology such as immune defense against intracellular microorganisms, including viruses, and apoptosis (for review see Balligand and Cannon, 1997). Although some or all of these phenomena may bear significantly on the contractile responsiveness of the intact heart, including of the heart *in vivo*, we will restrict our review on those effects of NO specifically produced by iNOS on the contractile responsiveness to β -adrenergic stimulation.

Cellular elements of the immune system have long been suspected to play a role in mediating the global myocardial dysfunction characteristic of septic shock, cardiac allograft rejection, and some forms of idiopathic cardiomyopathy (Lange and Schreiner, 1992). However, more recent work indicates that direct cell-mediated cytotoxicity is not required to induce myocardial depression in experimental models of sepsis in animals or contractile dysfunction in isolated ventricular myocytes exposed to inflammatory mediators, in-

cluding sera from patients with septic shock (Gulick *et al.*, 1988, 1991; Reilly *et al.*, 1989; Natanson *et al.*, 1989). Cell-free supernatants obtained from activated lymphocyte or macrophage cultures reversibly inhibit the expected increase in cAMP and concomitant positive inotropic responses of ventricular myocytes to the β -adrenergic agonist isoproterenol, but they have no effect on basal cAMP levels or on baseline contractile function (Gulick *et al.*, 1988, 1991). This effect of activated immune-cell-conditioned medium on myocyte responsiveness to β agonists is not immediate, but requires hours to become apparent (Lange and Schreiner, 1992).

Several cytokines that are known to be present in medium conditioned by activated immune cells have been shown to induce the synthesis of the inducible isoform of nitric oxide (iNOS) in a number of cell types and tissues (Leone *et al.*, 1991; Scott-Burden *et al.*, 1992; Xie *et al.*, 1992) including in cardiac myocytes, as mentioned above.

iNOS AND β -ADRENERGIC STIMULATION

Since NO produced by constitutive eNOS in response to β -adrenergic agonists has been shown to exert a negatively inotropic, countervailing effect on cardiac myocyte contraction, subsequent experiments examined whether induction of iNOS with the resultant production of large quantities of NO would also modulate the contractile response to β -adrenergic stimulation in these cells.

Myocyte Contractile Function Following Exposure to Macrophage-Conditioned Medium Given the importance of an appropriate contextual "network" for the action of cytokines in many tissues, a first approach was to investigate the ability of physiological, species-specific combinations of inflammatory mediators to induce contractile dysfunction in adult cardiomyocytes. These were obtained from the supernatant of cultures of rat alveolar macrophages prestimulated with lipopolysaccharide (LPS).

In the absence of isoproterenol, exposure of primary isolates of adult rat ventricular myocytes to alveolar macrophage-conditioned medium for 24 hours affected neither contractile amplitude nor velocities of contraction or relaxation compared with myocytes incubated in a control, defined medium alone, whether or not the conditioned medium was obtained from macrophages preincubated with endotoxin. However, when myocytes were preincubated in medium containing supernatant from endotoxin-activated alveolar macrophage cultures, there was a marked decline in the amplitude of contraction in response to isoproterenol, as well as comparable declines in the velocities of shortening and relengthening. Importantly, addition of L-NMMA to myocytes preincubated in macrophage-conditioned medium fully restored the positive inotropic response of myocytes to isoproterenol.

This diminished inotropic response to isoproterenol only became apparent after a minimum of 12 to 16 hours of preincubation of myocytes with LPS-activated, macrophage-conditioned medium, consistent with increased synthesis of the inducible isoform of NO synthase in response to one

or more inflammatory mediators produced by activated macrophages (Knowles and Moncada, 1992; Balligand *et al.*, 1993b; Schulz *et al.*, 1992). This is in contrast to data previously reported by Finkel *et al.* (1992), who demonstrated that several recombinant cytokines, including TNF- α , IL-2, and IL-6, had negative inotropic effects within 2 to 3 min when added to superfusion medium bathing an isolated hamster papillary muscle preparation. This negative inotropic effect was apparent in the absence of any cardiotoxic agents, including adrenergic agonists, and it could be prevented by addition of L-NMMA to the superfusion medium. As the rapid onset of the negative inotropic effect is inconsistent with increased transcription and synthesis of a calcium-insensitive, inducible isoform of NO synthase, it is possible, as these authors suggest (Finkel *et al.*, 1992), that these cytokines resulted in activation of a calcium/calmodulin-responsive constitutive isoform of NO synthase in papillary muscle.

Single Cell Analysis of iNOS Activity and Contractile Effect Although it is likely that induction of NO synthase within the myocytes themselves was the source of NO responsible for the negative inotropic response to isoproterenol, microvascular endothelial cells from adult rat ventricular tissue also respond to soluble inflammatory mediators in the endotoxin-activated alveolar macrophage-conditioned medium, suggesting that NO released by these cells may contribute to the contractile dysfunction of adjacent myocytes. To definitively characterize the functional significance of iNOS expression within cardiac myocytes themselves, the effect of various pharmacological modulators of NOS activity was examined on the contractile shortening and NO production in isolated single ventricular myocytes, as analyzed by both video-motion microscopy and a NO-specific porphyrinic microsensor.

The NO microsensor technology has been described and validated in both tissue and cell culture systems, with a detection limit of approximately 10 nM. The amperometric mode used in these experiments had been successfully used to measure the kinetics of NO release from endothelial cells in response to eNOS activation by agonists that increase intracellular calcium. In contrast with eNOS, the activity of the largely calcium-insensitive iNOS is not rapidly regulated by changes in intracellular calcium, but is usually sustained for several hours after it has been induced. In order to take advantage of the sensitivity and time resolution of the electrode, the cells were deprived of L-arginine, the substrate for NOS, in order to reduce their production of NO, and then the amino acid was abruptly reintroduced to observe an outburst of NO release with an acceptable signal-to-noise ratio.

Rapid changes of an analytical current could be obtained in the amperometric mode if cytokine-treated myocytes were first incubated for 4 hours in L-arginine-depleted medium and the recording initiated in buffer before and after L-arginine, the substrate for NO synthase, was reintroduced. Experimen-

tal conditions were then established that permitted recordings to be obtained of NO release from a single L-arginine-depleted cardiac myocyte. For these experiments, L-arginine was reintroduced through a micropipette with the injection parameters designed to deliver the substrate to a single cell. Following exposure to recombinant cytokines and a 4-hour incubation in L-arginine-depleted medium, the microinjection pipette and NO microsensor were aligned adjacent to an isolated rod-shaped cardiomyocyte. The preparation was then left until a stable baseline was observed for at least 10 min. The subsequent microinjection of L-arginine resulted in an increase of the NO signal that gradually returned to baseline over 15 to 20 min. The mean estimated concentration of NO at the plasma membrane was 104 ± 15.8 nM. In comparison, control experiments performed using the same technique on single rat alveolar macrophages induced *in vitro* with LPS, as described above (Balligand *et al.*, 1993b), resulted in readings between 155 and 800 nM ($n = 3$). Other controls were performed with cardiac myocytes, prepared as described above, after microinjection of D-arginine or L-arginine following a 4-hour incubation with the L-arginine analog L-NMMA, both conditions in which no signal could be recorded.

Finally, a typical decline in inotropic responsiveness to isoproterenol was also observed under experimental conditions in which NO release was detected from single cardiac myocytes with the NO microsensor. In other words, decline in responsiveness followed readdition of L-arginine, but not D-arginine, thereby reproducing the paradigm observed in cardiomyocytes exposed to LPS-activated macrophage-conditioned medium (Balligand *et al.*, 1993b, see earlier).

Myocyte Contractile Function in Short-Term Heterotypic Cardiac Myocyte–Microvascular Endothelial Cell Cultures: Effect of IL-1 β To determine whether coronary microvascular endothelial cells (CMEC), after exposure to a specific immunologic stimulus, could generate sufficient nitric oxide to affect the function of adjacent cardiac myocytes, a coculture system was designed in which myocyte contractile function was used as a bioassay. Freshly isolated adult rat ventricular myocytes were plated directly on confluent, serum-starved low passage CMEC primary cultures that had been established either in control medium or in the presence of IL-1 β (4 ng/ml). This concentration of the cytokine had clearly been shown to induce iNOS activity in microvascular endothelial cells (Ungureanu-Longrois *et al.*, 1995a). Coverslips containing the myocyte–CMEC cultures were then studied by videomicroscopy both at baseline and after perfusion with isoproterenol.

IL-1 β alone did not have any effect on baseline or on isoproterenol-stimulated contractile function in cardiac myocytes after a 24-hour exposure (Ungureanu-Longrois *et al.*, 1995a; see earlier). However, cardiac myocytes plated on IL-1 β -pretreated endothelial cells had a significantly reduced inotropic response to isoproterenol compared with myocytes plated on control endothelial cell cultures (Ungureanu-

Longrois *et al.*, 1995b). Furthermore, L-NMMA restored the responsiveness to isoproterenol of myocytes plated on IL-1 β -pretreated endothelial cells, demonstrating that NO production from the endothelial cells was responsible for the decreased contractile response of cocultured myocytes.

POSTTRANSLATIONAL REGULATION OF iNOS ACTIVITY AFFECTS NO-DEPENDENT REGULATION OF CARDIAC CONTRACTION: L-ARGININE TRANSPORT

Among the constituents of the defined medium routinely used for the culture of adult rat ventricular myocytes, it was noted that insulin was required for NO production, as detected by nitrite release in cytokine-pretreated myocytes, although insulin had no effect on the extent of induction of iNOS mRNA or on maximal enzyme activity in myocyte cell lysates. Insulin was also required for the decrease in contractile responsiveness to isoproterenol to be manifest (Ungureanu-Longrois *et al.*, 1995a). Further experiments by W. Simmons and colleagues demonstrated that insulin significantly increased transmembrane L-arginine transport in myocytes and microvascular endothelial cells. This increase in NOS substrate availability could explain the increase in enzyme activity in intact cells, as well as the dependence on insulin for NO-mediated contractile dysfunction in myocytes (Simmons *et al.*, 1996).

Intracellular Mechanisms of Action of NO in Cardiac Muscle Cells¹

The effects of NO can be distinguished between those dependent on cyclic GMP formation following the activation of guanylyl cyclase and those that are independent of cyclic GMP. This does not preclude from the possibility that NO acts simultaneously through both mechanisms, depending on the intra- or extracellular source, the intracellular compartmentation of NOS isoforms, the amount of NO produced, and local redox conditions, all of which are likely to impact on NO reactivity with its intracellular targets (Fig. 5). These restrictions aside, exogenous NO donor drugs as well as NOS inhibitors have been very useful to advance the understanding of the functional interaction between the NO synthase pathway and β -adrenergic signaling, which will only be considered briefly here.

Cyclic GMP-Dependent Mechanisms

ENHANCEMENT OF β -ADRENERGIC RESPONSE

Cardiomyocytes from most mammalian species express the type III isoform of cyclic nucleotide phosphodiesterases, or PDE3, which is allosterically inhibited by cyclic GMP. PDE3 has been implicated in mediating NO-induced in-

creases in cyclic AMP and the subsequent activation of L-type calcium current and inotropy in isolated cardiac myocytes in rodents and in human atria (Kirstein *et al.*, 1995; Méry *et al.*, 1993). Low concentrations of NO donors also induced a moderate positively inotropic effect in adult rat ventricular myocytes (Kojda *et al.*, 1996; Preckel *et al.*, 1997) and in open chest dog hearts (Preckel *et al.*, 1997) as mentioned previously. In feline cardiac myocytes, the same pathway may mediate a rebound increase in L-type calcium current, calcium transients, and contraction after the abrupt removal of acetylcholine (Wang and Lipsius, 1995; Wang *et al.*, 1998).

Intracellular cyclic AMP levels might also be regulated "upstream" from the phosphodiesterases, for example, by direct regulation of adenylyl cyclase activity or its coupling to β -adrenoceptors through the stimulatory G protein α_s . Previous studies in lymphocytes also have shown that NO can modulate the GTPase activity of the small G protein p21-Ras (Lander *et al.*, 1995, 1997). NO-dependent increases in cyclic GMP may also potentiate cardiac contraction through mechanisms independent of cyclic AMP. Accordingly, Galione and colleagues (1991) provided evidence that intracellular cyclic GMP could activate calcium release from the ryanodine channel through activation of ADP ribosyl cyclase and subsequent increases in cyclic ADP ribose. More recently, these authors demonstrated that the pathway may be operative to increase calcium release from the sarcoplasmic reticulum in intact guinea pig cardiomyocytes (Iino *et al.*, 1997).

DECREASE IN β -ADRENERGIC RESPONSE

Cardiac myocytes from a variety of species also express a cyclic GMP-activated phosphodiesterase, or PDE2. A rat isoform of PDE2 was identified as a main cyclic nucleotide phosphodiesterase isoform in sinoatrial node cells from rabbits (Han *et al.*, 1995), where the muscarinic cholinergic accentuated antagonism on L-type calcium current was also completely abolished by a specific PDE2 inhibitor, EHNA. A similar pathway was found to be operative in atrioventricular and ventricular myocytes from rabbits and rats (Balligand *et al.*, 1995; Han *et al.*, 1995, 1996).

Combined with the notion that cardiomyocytes may express both PDE2 and PDE3, the coexistence of these functionally opposed pathways provides a explanation for the bidirectional effect of NO or cyclic GMP in response to β -adrenergic stimulation of L-type calcium current and contraction (Ono and Trautwein, 1991; Kojda *et al.*, 1996), as mentioned earlier. In circumstances where high levels of intracellular cyclic GMP are produced, such as those generated on NO production by iNOS, the resultant activation of PDE2 leads to an attenuation of isoproterenol-stimulated increase in cyclic AMP as well as the shortening of adult rat myocytes in culture (Joe *et al.*, 1998; Balligand *et al.*, 1993b). As mentioned before, a similar mechanism may be operative for the attenuation of β -adrenergic responsiveness by NO produced endogenously by eNOS through its ability to increase intracellular cyclic GMP following adrenergic stimulation, as

¹ The paragraphs in this section were reproduced, in part, from a previous publication (Balligand, J. L., *Cardiovascular Research*, 1999, 43, 607–620) with permission from Elsevier Science.

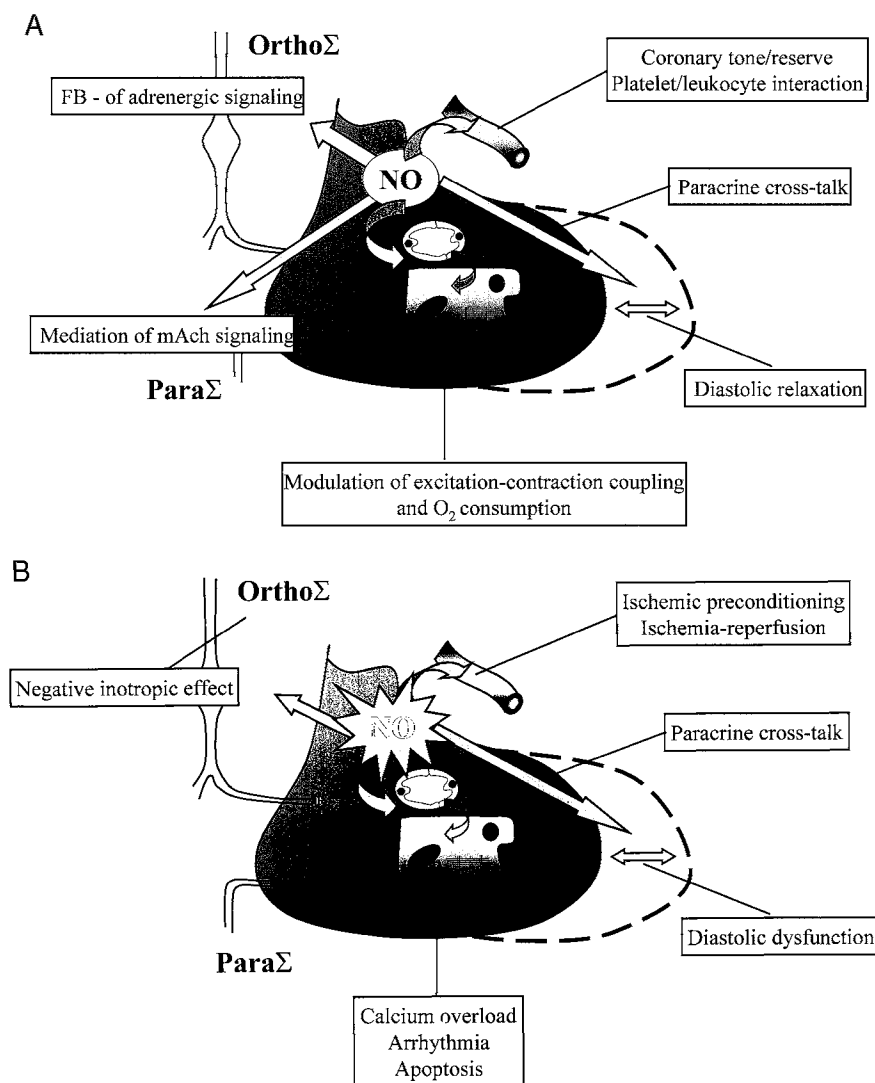

Figure 5 Modulation of cardiac contraction by NO in (A) normal heart and (B) diseased heart.

demonstrated in rat and human ventricular tissue (Gauthier *et al.*, 1998a; Joe *et al.*, 1998). The latter phenomenon could provide an explanation for the fact that NOS inhibitors affect myocyte contractile shortening only when they have been prestimulated with β -adrenoceptor agonists (Balligand *et al.*, 1993a,b).

In addition to activating PDE2, cyclic GMP can attenuate cardiomyocyte contraction by activating a cyclic GMP-dependent protein kinase (PKG) isoform. This protein may in turn decrease the L-type calcium current stimulated by cyclic AMP-dependent PKA (Méry *et al.*, 1991; Wahler and Dollinger, 1995), or downregulate the contractile responses of myofilament proteins independently of changes in calcium transients (Shah *et al.*, 1994; Yasuda and Lew, 1997; Goldhaber *et al.*, 1996). The latter mechanism, however, is unlikely to account for the attenuation of β -adrenergic responsiveness since it was shown to be abrogated on concomitant treatment of ventricular myocytes with isoproterenol (Shah *et al.*, 1994), as mentioned earlier.

Finally, using the model of *in vivo* endotoxin treatment, Sulakhe and colleagues studied in parallel the contractile responses to isoprenaline in isolated papillary strips and a variety of intracellular target proteins in cardiomyocytes isolated from endotoxin-injected rats. Attenuated contraction in response to isoprenaline in isolated muscles was paralleled by increased iNOS activity in myocytes, while the effect of phosphorylation of phospholamban and troponin-inhibitory subunit was decreased compared to extracts from control rats (Sulakhe *et al.*, 1996). These results would argue against an effect of iNOS-derived NO on PKG-mediated phosphorylation of troponin I to desensitize cardiac myofilaments to calcium (Yasuda and Lew, 1997).

Cyclic GMP-Independent Mechanisms

The oxidation of critical thiol residues on regulatory proteins by NO or by other NO-derived radicals (such as peroxynitrite) may account for some of the actions of NO on

cardiac function. These effects are more likely to be produced in the presence of high concentrations of NO and superoxide anion, such as following induction of inflammatory cytokines and iNOS in the setting of increased oxidative stress. Among the contractile regulatory proteins sensitive to oxidation, the cardiac calcium release channel (ryanodine receptor) and the L-type calcium channel have been shown to be possible targets (Xu *et al.*, 1998; Campbell *et al.*, 1996; Hu *et al.*, 1997; Zahradnikova *et al.*, 1997). NO and other oxidative metabolites may also regulate key enzymes regulating oxygen consumption and ATP generation within heart muscle, including creatine kinase and cytochrome C oxidase (for reviews, see Balligand and Cannon, 1997; Kelly *et al.*, 1996). These observations emphasize the need to verify that any effect produced with pharmacological concentrations of NO donors is representative of the action of endogenously generated NO within the temporal and spatial constraints imposed by the subcellular localization of each specific NOS isoform.

NOS and Contractile Dysfunction

Numerous studies have examined the involvement of either eNOS or iNOS in the depressed myocardial responsiveness to catecholamines in heart dysfunction from different etiologies, including sepsis, transplant rejection, and ischemic or dilated cardiomyopathies.

All of these pathologies have been shown to be accompanied by increased expression of iNOS in the myocardium, albeit with considerable variability regarding the abundance of iNOS protein and the predominant cellular source, as mentioned earlier. In contrast, although changes in the abundance of eNOS mRNA or protein may not be unidirectional in heart failure of all etiologies, it was shown to be reduced in end-stage failing hearts in ischemic and dilated cardiomyopathies (Drexler *et al.*, 1998) consistent with findings at the protein level (Gauthier *et al.*, 1998b).

eNOS and Arrhythmia

The changes in eNOS abundance noted earlier may bear on other important aspects of β -adrenergic stimulation of the heart. Aside from changes in inotropic parameters, we have observed that treatment of electrically paced human atrial strips with the NO synthase inhibitor, L-NMMA enhanced the arrhythmogenic effect of submaximal concentrations (10 nM) of isoproterenol, as manifested by the occurrence of aftercontractions (Gauthier *et al.*, 1998b). A role for eNOS in controlling the threshold for adrenergically induced ventricular arrhythmia is also supported by the following observations. In open chest dogs with acute coronary artery occlusion, Fei and colleagues (1997) showed that intrapericardial perfusion with L-arginine to increase NOS activity (as reflected by an increased NO effluent in the coronary sinus) protected the myocardium against the occurrence of ventricular fibrillation. More recently, the role of myocyte-specific

eNOS was directly assessed in the control of ouabain-induced arrhythmias by comparing the occurrence of aftercontractions and I_{ti} current between ventricular myocytes from eNOS $-/-$ mice and from wild-type controls. Ouabain induced more arrhythmic contractions and I_{ti} currents in eNOS $-/-$ myocytes; these were efficiently prevented by the exogenous administration of S-nitrosoacetylcysteine, a NO donor (I. Kubota, X. Han, and R. A. Kelly, 2000, unpublished results), thereby supporting a role for myocyte eNOS in controlling the arrhythmic threshold. These observations may also explain the higher incidence of ventricular arrhythmias in circumstances where eNOS is downregulated. We previously showed such downregulation after intramyocardial elevation of cyclic AMP with drugs such as milrinone commonly employed in the treatment of end-stage heart failure (Belhassen *et al.*, 1996). The notion that eNOS may be downregulated in the failing myocardium (see later) may further explain the arrhythmogenic potential of inotropic drugs in patients with heart failure.

eNOS in Hypertrophic Myocardium

In contrast to idiopathic or ischemic dilated cardiomyopathies, eNOS expression may not be downregulated until the late, failing stage of hypertensive cardiomyopathy (and may even be transiently upregulated at earlier stages). In a study on isolated hypertrophic hearts and myocytes from rats with aortic stenosis, Bartunek and colleagues found that eNOS mRNA and protein levels were unchanged compared to controls but that chronic treatment with L-arginine, the substrate for NOS, significantly increased myocardial cyclic GMP levels. Despite the absence of any significant change in the development of cardiac hypertrophy, this chronic treatment with L-arginine blunted left ventricular systolic pressure and the contractile response to isoproterenol in both isolated hypertrophic hearts and myocytes (Bartunek *et al.*, 1998). In another study on isolated ventricular strips from hypertrophic hearts of either spontaneously hypertensive (SHR) nephrectomized or suprarenal aortic banded rats, treatment with 10 μ M of SNAP failed to reproduce the rightward shift of the concentration response curve for isoprenaline characteristically observed in control animals (Kotchi *et al.*, 1998). Such discrepancies again emphasize the need for caution when extrapolating the effects of exogenous NO donor drugs to endogenously produced NO.

Based on the previous observations that NO inhibits vascular smooth muscle cell proliferation, several authors have examined the potential influence of nitric oxide on the growth-promoting effects of norepinephrine in cardiac myocytes and fibroblasts. In one of these studies, Calderone and his colleagues found that inhibition of NO synthase with L-NMMA potentiated norepinephrine-stimulated protein synthesis in cultured cardiomyocytes. Atrial natriuretic peptide and the NO donor SNAP also suppressed adrenergically stimulated growth of myocytes and fibroblasts, an effect attributed to a cyclic GMP-dependent inhibition of calcium influx secondary to α_1 -adrenergic receptor activation by the

catecholamines (Calderone *et al.*, 1998). These findings have been corroborated by the observation that NOS inhibition *in vivo* in rats augmented indices of cardiomyocyte hypertrophy (Devlin *et al.*, 1998), even though the experiments did not distinguish direct effects of NOS inhibition on cardiomyocytes from indirect effects secondary to increases in blood pressure in the animals.

Potential Role of iNOS in the Myocardial Depression of Heart Failure

When the response to increasing concentrations of isoproterenol was examined in isolated, electrically stimulated human ventricular myocytes *in vitro*, the response to β -adrenoceptor stimulation normalized to the maximum shortening induced by high calcium was depressed in myocytes from failing heart compared to those from nonfailing hearts. However, treatment with the NOS inhibitor L-NMMA failed to increase the isoproterenol-mediated rise in calcium in myocytes from failing hearts under the particular experimental conditions of this study (Harding *et al.*, 1998). In contrast, in another study on the isometric contractions of human left ventricular trabeculae from failing hearts, muscle strips exhibited a decreased responsiveness to β -adrenergic stimulation manifested by a depressed peak tension and abbreviated early relaxation time. Importantly, these alterations not only were significantly correlated with the extent of iNOS activity and iNOS mRNA abundance but also were corrected on treatment of the left ventricular trabeculae with L-NMMA (Drexler *et al.*, 1998). As mentioned earlier, the inotropic effect of dobutamine was similarly attenuated on intracoronary infusion of substance P (which is expected to increase paracrine production of NO) both in nonfailing transplant recipients and in patients with dilated nonischemic cardiomyopathy (Prendergast *et al.*, 1998). In patients with dilated cardiomyopathy, Hare and colleagues observed a potentiation of the inotropic response to peripheral infusion of dobutamine after intracoronary administration of L-NMMA (Hare *et al.*, 1995, 1998b). The contrast with unaltered responsiveness to the catecholamine in normal patients was interpreted as an increased sensitivity of the *in situ* failing heart to NOS inhibition. Other studies on cardiomyocytes isolated from animal models of heart failure lend support to the same paradigm (Yamamoto *et al.*, 1997). Finally, in isolated atrial and ventricular strips from human failing and nonfailing hearts, the ability of exogenous NO donors to produce quantitatively and qualitatively similar effects adds further evidence for a significant role of NO as a regulator of β -adrenergic responsiveness in the heart (Flesch *et al.*, 1997).

Cardiology, University Hospital, Zürich, Switzerland*

SMALL ARTERIES PLAY AN IMPORTANT ROLE IN THE REGULATION OF PERIPHERAL VASCULAR RESISTANCE. THE ENDOTHELIUM OF RESISTANCE ARTERIES REGULATES VASCULAR FUNCTION BY WAY OF ITS BARRIER ROLE, BY INTERACTION WITH CIRCULATING CELLS SUCH AS PLATELETS, WHICH MAY RELEASE VASOACTIVE OR GROWTH REGULATING AGENTS, AND BY PRODUCTION OF SUBSTANCES THAT MODULATE VASCULAR TONE AND SMOOTH MUSCLE CELL GROWTH. IMPORTANT MEDIATORS ARE NITRIC OXIDE (NO) AND, ESPECIALLY IN SMALL ARTERIES, ENDOTHELIUM-DEPENDENT HYPERPOLARIZING FACTOR (EDHF) AND ENDOTHELIN-1. THE ENDOTHELIUM IS AN OBVIOUS TARGET ORGAN OF CARDIOVASCULAR RISK FACTORS. ACCORDINGLY, FUNCTIONAL ALTERATIONS DO OCCUR WITH AGING, HYPERTENSION, AND HYPERCHOLESTEROLEMIA. ALL CONDITIONS ARE ASSOCIATED WITH A DECREASED BASAL AND SIMULATED RELEASE OF ENDOTHELIUM-DERIVED NO. ON THE OTHER HAND, THE PRODUCTION OF CYCLOOXYGENASE-DEPENDENT ENDOTHELIUM-DERIVED CONTRACTING FACTOR AND ENDOTHELIN-1 APPEARS TO BE INCREASED, WHICH OFFSETS THE EFFECTS OF NO AND EDHF. THUS, THE ENDOTHELIUM IS AN IMPORTANT REGULATOR OF THE MICROCIRCULATION. ALTERATIONS OF ENDOTHELIAL FUNCTION MAY HAVE IMPORTANT CLINICAL IMPLICATIONS FOR THE PATHOGENESIS OF CARDIOVASCULAR DISEASE.

Introduction

The vascular endothelium is strategically positioned between the bloodstream and the vascular smooth muscle cells (VSMC) and is a source of vasoactive factors such as nitric oxide (NO), endothelium-dependent hyperpolarizing factor (EDHF), prostacyclin, prostaglandins, and endothelin (Furchgott and Zawadzki, 1980; Lüscher and Vanhoutte, 1990). NO is an important vasodilator agent that counteracts tonic vascular constriction of neuronal, endocrine, or local origin. Furthermore, NO also contributes inhibition of platelet function and thus plays an important functional role in maintain-

ing vascular homeostasis. This review focuses on the role of this potent vasodilator, which regulates vascular tone and structure of the microcirculation under physiological conditions as well as in aging, hypertension, and hypercholesterolemia. Furthermore, modulation of endothelium-derived NO by pharmacotherapy will also be discussed.

Endothelium-Derived NO

Nitric oxide is a diffusible substance with a short half-life of a few seconds (Fig. 1, right) (Ignarro *et al.*, 1987; Palmer *et al.*, 1987). It is formed from L-arginine by oxidation of its guanidine–nitrogen terminus (Palmer *et al.*, 1988), requiring cofactors such as oxygen, NADPH, 5,6,7,8-tetrahydrobiop-

¹ Present address: Department of Anesthesiology and Pharmacology, Mayo Clinic, Rochester, Minnesota 55905.

Figure 1 Endothelium-derived relaxing factors (right) and endothelium-derived contracting factors (left). Endothelial cells form nitric oxide (NO) from L-arginine via the activity of the endothelial NO synthase (eNOS), and it causes increases in cyclic 3',5'-guanosine monophosphate (cGMP) in VSMC and platelets, which in turn mediates relaxation and platelet inhibition, respectively. In addition, prostacyclin (PGI₂) causes relaxation via a cyclic adenosine monophosphate (cAMP)-dependent mechanism. Stimulation of the cyclooxygenase-1 pathway by receptor-operated agonists such as acetylcholine (Ach) and serotonin (5-HT), or by physical forces, can lead to the formation of prostaglandin H₂ (PGH₂), thromboxane A₂ (TXA₂), or superoxide anions (O₂⁻), which in turn elicit direct vasoconstrictions and also inactivate NO. In addition, ET-1 and ET-3 can activate ET_B receptors on the endothelial cell membrane, which are linked to the production of NO and PGI₂. ECE-1, endothelin converting enzyme-1; TX, thromboxane; M, muscarinerg; S, serotonin; circle, receptors. Adapted from Lüscher *et al.*, *Hypertension* **19**, 117–130 (1992); with permission.

terin, and Ca²⁺/calmodulin (Bredt *et al.*, 1990; Ignarro, 1990; Moncada *et al.*, 1991). The formation of NO occurs via nitric oxide synthase (NOS), which either is expressed constitutively or can be induced by cytokines and other stimuli (Bredt *et al.*, 1990; Förstermann *et al.*, 1991; Pollock *et al.*, 1991). So far, three different isoforms of NOS have been described, namely, neurohumoral (nNOS or NOS I), inducible (iNOS or NOS II), and endothelial NOS (eNOS or NOS III) (Moncada *et al.*, 1997).

Most of eNOS appears to be bound to the endothelial cell membrane, whereas only a small fraction is of cytosolic origin (Sessa *et al.*, 1992). Receptor-dependent agonists (i.e., acetylcholine, bradykinin, substance P, and platelet-derived products such as thrombin and adenosine diphosphate) increase intracellular free Ca²⁺, which in turn activates eNOS and elicits endothelium-dependent relaxations (Fig. 1, right) (Lüscher and Vanhoutte, 1990). The endothelial L-arginine–NO pathway is further activated by shear forces exerted by the circulating blood cells, thereby causing flow-dependent vasodilation (Pohl *et al.*, 1986).

Relaxations in response to the abluminal release of endothelium-derived NO are associated with stimulation of soluble guanylyl cyclase and in turn formation of cyclic guanosine 3',5'-monophosphate (cGMP) in VSMC; this in turn reduces intracellular calcium and dephosphorylates myosin light chains (Rapoport *et al.*, 1983). Soluble guanylyl cyclase, also present in platelets, is activated by the luminal

release of endothelium-derived NO (Busse *et al.*, 1987), and this limits adhesion and aggregation (Fig. 1) (Radomski *et al.*, 1990). Therefore, endothelium-derived NO causes both vasodilation and platelet deactivation, and it thereby represents an important antithrombotic feature of the endothelium.

Importance of Endothelium-Derived NO in the Microcirculation

Nitric oxide also regulates vascular tone in small arteries. Indeed, in intramyocardial porcine coronary arteries, L-N^G-monomethylarginine (L-NMMA) causes endothelium-dependent contraction (Tschudi *et al.*, 1991a). In the perfused porcine ophthalmic circulation, L-NMMA reduces flow by about 40% (Meyer *et al.*, 1993). Accordingly, in the human forearm circulation (Joannides *et al.*, 1995a) and coronary microcirculation (Quyyumi *et al.*, 1995), L-NMMA reduces flow considerably (Fig. 2). After prolonged ischemia in the human forearm, flow increases rapidly. The maximal increase in flow after ischemia is not affected by L-NMMA, indicating that it is metabolically mediated (Joannides *et al.*, 1995b; Meredith *et al.*, 1996). However, the half-life of the hyperemic response is markedly reduced by L-NMMA. Thus, NO markedly contributes to the maintenance of flow-dependent vasodilation in the microvasculature.

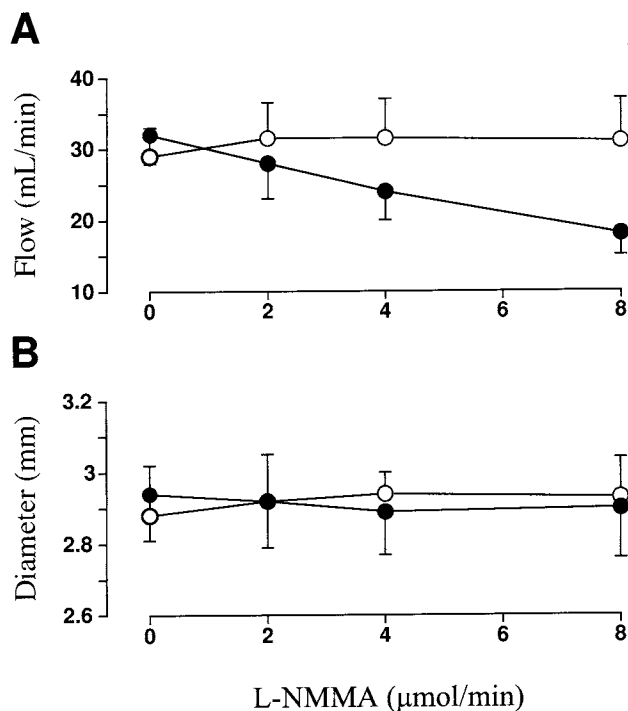

Figure 2 Mean radial blood flow (A) and mean internal diameter (B) during control period (open circles) and after infusion of increasing doses of L-N^G-monomethyl arginine (L-NMMA; filled circles) in healthy volunteers. L-NMMA dose-dependently decreases radial blood flow after 8 μmol/min L-NMMA ($p < 0.01$) but does not affect radial artery internal diameter. Values are means \pm SEM of 11 subjects. Adapted from Joannides *et al.*, (1995a), Role of basal and stimulated release of nitric oxide in the regulation of radial artery caliber in humans. *Hypertension* 26, 327–331, with permission.

Furthermore, NO also plays a crucial role in the regulation of blood pressure (Gardiner *et al.*, 1990). Indeed, when infused intravenously, inhibitors of NOS such as L-NMMA or N^ω-nitro-L-arginine methylester (L-NAME) induce long-lasting increases in blood pressure and vascular resistance in the rabbit and in humans (Haynes *et al.*, 1993). This demonstrates that the resistance circulation is in a constant state of vasodilation due to the continuous basal release of picomolar quantities of NO by the vascular endothelium.

Although NO is an important modulator of vascular tone, not all endothelium-dependent relaxations are prevented by inhibitors of the L-arginine pathway. In epicardial coronary arteries, L-NMMA, hemoglobin, or methylene blue only partially prevent endothelium-dependent relaxations to bradykinin. These NO-independent relaxations are even more prominent in intramyocardial arteries (Tschudi *et al.*, 1991a). In mesenteric resistance arteries, L-NMMA, methylene blue, and hemoglobin only partially inhibit endothelium-dependent relaxations to acetylcholine (Dohi *et al.*, 1990; Nagao *et al.*, 1992), an indication that NO only in part accounts for endothelium-dependent responses. Precontraction with depolarizing solution, on the other hand, markedly reduces NO-independent relaxations. Because these conditions cause VSMC to become transiently hyperpolarized via the activation

of an adenosine triphosphate-sensitive K⁺ channel (Standen *et al.*, 1989) and/or Na⁺, K⁺-adenosine triphosphatase (Feletou and Vanhoutte, 1988), an endothelium-dependent hyperpolarizing factor (EDHF) has been proposed. Thus, the importance of endothelium-dependent hyperpolarizing factor for endothelium-dependent relaxations increases as the vessel size decreases in both the coronary and mesenteric circulations (Nagao *et al.*, 1992; Hwa *et al.*, 1994; Shimokawa *et al.*, 1996).

In addition to NO, prostacyclin is released by endothelial cells in response to several mediators, shear stress, and hypoxia (Fig. 1) (Yang *et al.*, 1992; Chida and Voelkel, 1996). The platelet inhibitory effects of prostacyclin may be more important than its contribution to endothelium-dependent relaxation (Moncada *et al.*, 1977). Indeed, in mesenteric resistance arteries, indomethacin does not affect endothelium-dependent relaxations to acetylcholine (Dohi *et al.*, 1990). In the human forearm circulation, acetyl-salicylic acid also does not alter the increase in blood flow exerted by acetylcholine (Linder *et al.*, 1990). However, certain investigators found some reduction in flow-dependent vasodilation in the forearm with cyclooxygenase inhibition (Duffy *et al.*, 1998). In platelets, NO and prostacyclin synergistically inhibit the aggregation, suggesting that the activity of both mediators is required to exert full antiplatelet activity (Radomski *et al.*, 1987).

Interaction of NO with Endothelium-Derived Contracting Factors

Endothelium-derived NO not only causes vasodilation and inhibition of platelet aggregation but also can interact with endothelium-derived contracting factors at the level of both the endothelium and the VSMC.

Interaction with Endothelin

Endothelin-1 (ET-1) is a potent vasoconstrictor. Expression of messenger RNA and release of the peptide is stimulated by vasoconstrictor hormones, coagulation products, and cytokines (Fig. 1, left) (Yanagisawa *et al.*, 1988; Hahn *et al.*, 1990; Dohi *et al.*, 1992). On the other hand, NO as well as prostacyclin inhibit ET-1 production via a cGMP-dependent mechanism (Boulanger and Lüscher, 1990) and, furthermore, reduce ET-1-induced vasoconstriction in VSMC of mesenteric resistance arteries. This indicates that NO protects the microcirculation against contractions to ET-1 under physiological conditions (Dohi and Lüscher, 1990; Lüscher *et al.*, 1990a). ET-1 exerts its biological effects via activation of distinct specific ET receptors (Arai *et al.*, 1990; Sakurai *et al.*, 1990). One receptor type shows high selectivity to ET-1 and most likely represents the ET_A receptor on VSMC (Alberts *et al.*, 1994). The other type, the ET_B receptors, which are equally activated by ET-1 and ET-3, are present on endothelial cells linked to the formation of endothelium-derived NO and prostacyclin (de Nucci *et al.*, 1988; Warner

et al., 1989; Hirata *et al.*, 1993). Accordingly, in isolated rat perfused mesenteries, ET-1 produces concentration-dependent vasodilation that is unaffected by selective blockade of ET_A receptors but is abolished when both ET_A and ET_B receptors are blocked (Warner *et al.*, 1993; Takase *et al.*, 1995). Similarly, in the human forearm circulation, intraarterial ET-1 causes an initial vasodilation followed by vasoconstriction that is particularly pronounced at higher concentrations of the peptide (Kiowski, 1991). In isolated mesenteric resistance arteries of the rat, NO added directly or via acetylcholine from the endothelium can reverse ET-1-induced contraction (Dohi and Lüscher, 1990). In contrast, in the human forearm circulation, neither acetylcholine nor sodium nitroprusside blocks ET-1-induced vasoconstriction, but calcium antagonists do (Kiowski *et al.*, 1991).

Interaction with Cyclooxygenase-Derived Products

Most agonists stimulating the L-arginine–NO pathway in the endothelium also activate phospholipase A₂ and thereby lead to the formation of thromboxane A₂ (TXA₂) and prostaglandin endoperoxide H₂ (PGH₂) (Fig. 1) (Moncada and Higgs, 1986). Indeed, exogenous arachidonic acid induces endothelium-dependent contractions in different isolated rat vascular beds, which are prevented by indomethacin, a cyclooxygenase inhibitor (Toda *et al.*, 1988; Lüscher *et al.*, 1990b). TXA₂ and PGH₂ affect not only VSMC via the activation of TXA₂ receptors (Lang *et al.*, 1995) but also platelets, which aggregate and hence counteract the beneficial effects of NO and prostacyclin in both cell types (Gerritsen, 1996).

In addition, the cyclooxygenase pathway is a source of superoxide anions (O₂^{•-}) which can evoke endothelium-dependent contractions either by inactivating endothelium-derived NO (Gryglewski *et al.*, 1986) or by directly stimulating VSMC (Kukreja *et al.*, 1986; Katusic and Vanhoutte, 1989).

NO Derived from Vascular Smooth Muscle in Inflammation and Septic Shock

Vascular smooth muscle cells can generate large quantities of NO via induction of iNOS. iNOS is activated by cytokines or bacterial products such as endotoxin, interleukin-1, interferon, and tumor necrosis factor (Bernhardt *et al.*, 1991; Nava *et al.*, 1991; Schneider *et al.*, 1992; Hishikawa and Lüscher, 1998). The induction of iNOS by inflammatory mediators also explains the hyperemic response at sites of inflammation and of generalized septic shock in patients (Vallance *et al.*, 1989). Indeed, preliminary studies suggest a beneficial effect of NO inhibition under these conditions. After induction, contractions to norepinephrine are reduced dramatically *in vitro* (Fleming *et al.*, 1990), and blood pressure is markedly lowered *in vivo* (Nava *et al.*, 1992).

Role of NO in Cardiovascular Disease

Aging and the Microcirculation

Aging is a physiological process that is independent of cardiovascular risk factor. Direct measurements of NO with a porphyrinic sensor revealed marked reductions in the aorta, and to a lesser degree in resistance arteries, but no change in the pulmonary circulation (Tschudi *et al.*, 1996a). In perfused mesenteric resistance arteries of Wistar-Kyoto (WKY) rats, aging is associated with a reduced response to L-NMMA and acetylcholine (Dohi *et al.*, 1990; Moreau *et al.*, 1998a), although the changes appear less pronounced than in large conduit arteries. The inhibitory effect of the endothelium against contraction induced by norepinephrine decreases with age in rat mesenteric resistance arteries, suggesting reduced basal release of NO (Atkinson *et al.*, 1994). However, *in vivo* studies in Sprague-Dawley rats revealed that oral treatment with L-NAME increases blood pressure and renal vascular resistance (Reckelhoff and Manning, 1993). Furthermore, the vasoconstricting effects of L-NAME increase with age, suggesting, at least in this model, that in renal and systemic circulations basal release of NO may increase with age.

Since the endothelium-independent relaxation induced by the NO donor agent linsidomine does not change with age, the reduced response to the muscarinic agonist must be due to a decreased production and/or release of relaxing factor(s). Similarly, endothelium-dependent increase in coronary flow in response to acetylcholine decreases with age in the rat (Katano *et al.*, 1993) and in the human coronary (Zeiger *et al.*, 1993) and forearm circulation (Taddei *et al.*, 1995). Impaired vasodilation in cerebral arterioles of aged rats does not appear to be related to an increased production of a cyclooxygenase-derived constrictor substances (Mayhan *et al.*, 1990).

Alterations of the Microcirculation in Hypertension

The hallmark of hypertension is an increase in peripheral vascular resistance that is considered to be due to an increased vascular tone of small arteries. This could be related to (1) an increased release of constricting factors and/or (2) a decreased release of relaxing factors, as well as (3) changes in vascular structure (eutrophic and hypertrophic remodeling). In most experimental models of hypertension, high blood pressure is associated with impaired endothelium-dependent relaxations and appears to occur as blood pressure rises, hence, it is a consequence rather than a cause of hypertension (Lüscher, 1990). However, in the offspring of hypertensive patients, impaired endothelium-dependent vasodilation to acetylcholine even before the onset of high blood pressure has been reported (Taddei *et al.*, 1996).

The basal formation of NO, as assessed by the contractile effects of inhibitors of NO production, is reduced in established hypertension in spontaneously hypertensive rats (SHRs), renovascular hypertensive rats, and ren-2 transgenic rats (Dohi *et al.*, 1990, 1991; Tschudi *et al.*, 1994a). Indeed,

in the mesenteric resistance circulation, L-NMMA increases vasoconstrictor responses to norepinephrine more in normotensive WKY rats than in SHR (Dohi *et al.*, 1990). In ren-2 transgenic rats, endothelium-dependent contractions to L-NAME are markedly blunted as the duration of hypertension increases (Tschudi *et al.*, 1994a). In addition, the decrease in forearm arteriolar blood flow induced by L-NMMA is smaller in patients with untreated essential hypertension than in normotensive patients (Calver *et al.*, 1992).

In isolated perfused mesenteric arteries of genetic models of hypertension such as SHR or Dahl salt-sensitive rats and of experimental models such as renovascular or L-NAME-induced hypertension, endothelium-dependent relaxations are reduced (Dohi *et al.*, 1990, 1991; Moreau *et al.*, 1995; d'Uscio *et al.*, 1997). However, the mechanism of endothelial dysfunction differs in different models of hypertension. In the resistance circulation of SHR, the NO pathway is upregulated by a mechanism involving increased expression and activity of constitutive NO synthase and overproduction of NO (Fig. 3A) (Nava *et al.*, 1998). Moreover, the concentration of nitrate, the oxidative product of NO, is higher in SHR as compared to age-matched WKY rats (Fig. 3B). However, further study suggests that the level of cyclic GMP in mesenteric arteries is similar in SHR and in WKY, suggesting that NO is not sufficiently bioactive to stimulate the formation of cyclic GMP on VSMC and to maintain an adequate NO-dependent vasodilatory tone in spontaneous hypertension (Fig. 3C) (Nava *et al.*, 1998). This is likely to be due to an increased NO decomposition by superoxide anions. Indeed, experimental evidence using a porphyrinic microsensor for direct measurement of NO has demonstrated that in the presence of superoxide dismutase, a superoxide anion scavenger, NO release from isolated mesenteric resistance arteries is improved in stroke-prone SHR (Tschudi *et al.*, 1996b).

One possible explanation is an imbalance between production of superoxide anions and activity of superoxide dismutase in the vessel wall, or a dysfunction of NO synthase may be involved (Cosentino *et al.*, 1998). Thus, endothelial dysfunction is linked to an overproduction of endothelium-derived radicals that lead to the formation of peroxynitrite. In contrast, impaired endothelium-dependent relaxations seen in Dahl rats is due to the reduced activity of endothelial NO synthase (Hayakawa *et al.*, 1997; Hayakawa and Raij, 1997).

Although it is commonly assumed that impaired endothelium-dependent relaxations are related to a reduced formation or release of NO under certain conditions, this may also be due to an enhanced production of endothelium-derived contracting factors (Fig. 4). Indeed, the production of a cyclooxygenase-dependent endothelium-derived contracting factor such as $\text{PGH}_2/\text{TXA}_2$ is increased in the microcirculation of SHR and ren-2 transgenic rats and offsets the effects of NO in VSMC and platelets (Lüscher *et al.*, 1986, 1990b; Diederich *et al.*, 1990; Noll *et al.*, 1997). Similarly, in the human forearm circulation indomethacin increases but does not normalize the reduced vasodilator response of hypertensive patients to acetylcholine (Taddei *et al.*, 1993).

On the other hand, as NO antagonizes the release of ET-1 (Boulanger and Lüscher, 1990) and regulates the production of the peptide *in vivo* (Sventek *et al.*, 1996; Filep, 1997), NO deficiency leads to enhanced ET-1 formation. This imbalance between NO and ET-1 production could contribute to endothelial dysfunction in hypertension. Accordingly, chronic blockade of ET_A receptors normalizes blunted endothelium-dependent relaxations of small mesenteric arteries in hypertension (d'Uscio *et al.*, 1997).

Of note is the fact that not all hypertensive blood vessels and not all forms of hypertension exhibit alterations of

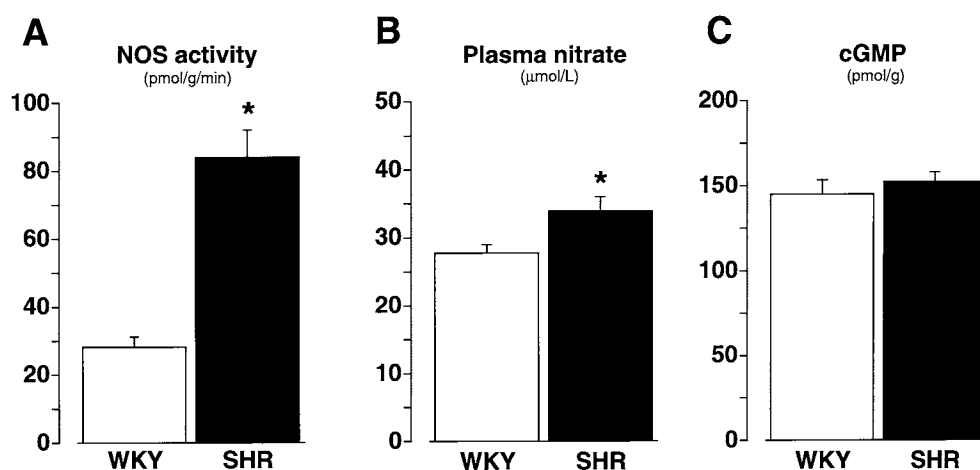

Figure 3 (A) Activity of the constitutive NO synthase (NOS) in mesenteric resistance arteries from Wistar-Kyoto (WKY) rats and spontaneously hypertensive rats (SHR). (B) Concentration of nitrate in plasma of WKY rats and SHR. Both vascular activity of NOS and overall release of NO, assessed by measuring plasma nitrate levels, appear to be significantly higher in tissues from SHR. (C) Levels of cyclic GMP (cGMP) in mesenteric resistance arteries from WKY rats and SHR. * $p < 0.05$ versus WKY rats. Adapted from Nava *et al.*, (1998), Alterations to the nitric oxide pathway in the spontaneously hypertensive rat. *Journal of Hypertension* 16, 609–615, with permission.

Figure 4 Proposed mechanisms of endothelial dysfunction in hypertension: Endothelium-dependent relaxations in genetic hypertension. In spontaneously hypertensive rats, nitric oxide synthase (NOS) activity is increased, but the biological activity of nitric oxide (NO) is reduced, possibly due to inactivation by superoxide anion (O₂⁻). In addition, the production of thromboxane A₂ (TXA₂) and prostaglandin H₂ (PGH₂) via cyclooxygenase (COX-1) is increased. Adapted from Lüscher *et al.*, Endothelium-derived contracting factors. *Hypertension* 19, 117–130, with permission. (1992).

the L-arginine–NO pathway. Indeed, in the coronary circulation of the SHR, a small amount of endothelial dysfunction is observed except in very old rats (Tschudi *et al.*, 1991b).

Effects of Hypercholesterolemia in the Microcirculation

Hypercholesterolemia and atherosclerosis interfere with the formation of NO in the endothelium and the response to it in VSMC. In hypercholesterolemia, a major risk factor predisposing to atherosclerosis, endothelial dysfunction is present before structural vascular changes occur (Freiman *et al.*, 1986; Celermajer *et al.*, 1992). Interestingly, oxidized low density lipoprotein (LDL), but not native LDL, reduces endothelium-dependent relaxations in coronary arteries (Tanner *et al.*, 1991; Zeiher *et al.*, 1991a). On the other hand, blood vessels exhibit enhanced vasoconstriction and increased adhesion of platelets and monocytes (Heistad *et al.*, 1984; Mathew *et al.*, 1997).

Although atherosclerosis primarily affects conduit arteries, endothelium-dependent relaxations are impaired not only in large arteries but also in the microcirculation of atherosclerotic animals and humans. In cremasteric vessels of the cholesterol-fed rabbit, cholinergic arteriolar vasodilation is defective (Yamamoto *et al.*, 1988). In coronary resistance arteries, hypercholesterolemia is associated with impaired endothelium-dependent relaxations to the agonists serotonin, bradykinin, and histamine (Chilian *et al.*, 1990; Sellke *et al.*, 1990a; Zeiher *et al.*, 1991b; Kuo *et al.*, 1992), indicating that the pathophysiological consequences of atherosclerosis may also extend into the microcirculation in humans.

Explanations for impaired endothelium-dependent vascular relaxations in hypercholesterolemia and atherosclerosis include (1) alterations in endothelial cell signal transduction [G_i-mediated pathways in particular (Shimokawa *et al.*, 1989)], (2) deficiencies in the substrate (L-arginine) for the enzyme NO synthase (Drexler *et al.*, 1991; Tanner *et al.*, 1991; Kuo *et al.*, 1992), (3) alterations in NO synthase activity or one of its cofactors (e.g., tetrahydrobiopterin deficiency) (Wever *et al.*, 1998), (4) excess destruction of NO by the superoxide anion (Münzel *et al.*, 1997; Hein and Kuo, 1998), and (5) reduced expression of the enzyme (Oemar *et al.*, 1998).

Increased local ET-1 levels, on the other hand, may also be an early marker for endothelial dysfunction. In this context, a relationship between plasma ET-1 levels and endothelial dysfunction in coronary circulation in early atherosclerosis in humans with atherosclerotic vascular disease has been reported (Lerman *et al.*, 1995). This study suggested that increased activation of the ET system—as demonstrated by increased plasma ET-1 levels—could mediate endothelial dysfunction and in turn enhance vasoconstrictor responses of blood vessels.

Other Vascular Diseases

In resistance arteries from diabetic animals and humans, several studies have shown impairment of NO-mediated endothelium-dependent relaxations as well as increased release of vasoconstrictor factors (Diederich *et al.*, 1994; Tribe *et al.*, 1998). This impairment is restored by PGH₂/TXA₂ receptor blockade or superoxide dismutase, indicating that the PGH₂ and/or superoxide anion generation contribute to endothelial dysfunction (Tesfamariam, 1994).

In Alzheimer's disease, the cerebral microcirculation undergoes specific biochemical changes. NO synthase activity is increased in the microvessels from affected brains and may be a potential neurotoxic mediator for the central nervous system (CNS). This could contribute to the susceptibility of neurons to injury and cell death in Alzheimer's disease (Dorheim *et al.*, 1994).

Hypoxia alters vascular tone in coronary resistance arterioles during prolonged ischemia, potentially through the modulation of endothelial cell metabolism as well as endothelial function. Indeed, hypoxia activates endothelial cNOS in coronary resistance arterioles and in turn increases the production of NO (Xu *et al.*, 1995).

NO and Vascular Structure

NO plays an important role in modulating vascular structure under physiological and pathophysiological conditions. In hypertension, resistance arteries adapt to the increased wall tension by changing their geometry. Accordingly, a reduced lumen diameter, an increased wall thickness, or both can normalize the excessive tension applied on the vessel wall and may then protect the microcirculation against the

blood pressure rise. Alterations of small artery structure may be mediated by eutrophic remodeling, a rearrangement of the same amount of vascular material around a smaller lumen, or hypertrophic remodeling (increase in cross-sectional area) of the vascular wall, or by a combination of both processes (Heagerty *et al.*, 1993). The vascular endothelium, by its anatomical position and by releasing several factors (see earlier), may influence the local vascular environment and modulate the changes of vascular geometry observed in the context of hypertension. Chronic inhibition of NO with L-NAME produces an elevation of blood pressure and is not associated with hypertrophic remodeling of cerebral and mesenteric arteries (Moreau *et al.*, 1995; Takase *et al.*, 1996), which would be expected if NO has a tonic inhibition on VSMC growth (Moreau *et al.*, 1998b), but is associated with eutrophic inward remodeling in proportion to the increase in blood pressure. Furthermore, prevention of hypertension in the L-NAME model by antihypertensive agents prevents inward remodeling, suggesting that NO blockade per se does not induce any vascular structural change *in vivo*.

Modulation of NO by Pharmacotherapy

Endothelial dysfunction seems to be a common feature of several pathological processes. Several drugs that could improve endothelial function or substitute factors needed for the NO pathway may have a potential advantage for protection and treatment of cardiovascular diseases.

Nitrovasodilators

Nitrovasodilators such as nitroglycerin, sodium nitroprusside, and linsidomine cause vasodilation by releasing NO from their molecules (Feelisch and Noack, 1987) and therefore acting through a mechanism identical with that of endogenous NO. Interestingly, vascular production of NO reduces the sensitivity of blood vessels to nitrovasodilators both in large conduit arteries (Pohl *et al.*, 1986; Lüscher *et al.*, 1990c) and in intramyocardial coronary resistance arteries (Tschudi *et al.*, 1991a). Similarly, in the human forearm circulation the response to sodium nitroprusside is enhanced after infusion of L-NMMA (Joannides *et al.*, 1995a). This suggests that the basal formation of NO in the endothelium reduces the sensitivity to nitrovasodilators also in the microcirculation.

The biotransformation of nitroglycerin is diminished in small coronary microvessels (60–100 μm in diameter) compared with larger coronary microarteries with 300 μm diameters (Sellke *et al.*, 1990b). This is likely to be due to a relative deficiency of available sulfhydryl groups or a lack of enzymes necessary for conversion of nitroglycerin to its active metabolites in small coronary resistance vessels (Moreau and Lüscher, 1997). This may explain why nitroglycerin is more effective in large arteries and veins than in the microcirculation.

Calcium Antagonists

Although the production of endothelium-derived NO in endothelial cells is associated with an increase in intracellular Ca^{2+} , calcium antagonists do not affect the release of the factor under acute conditions (Himmel *et al.*, 1993). Indeed, endothelial cells do not appear to possess voltage-operated calcium channels. There are reports, however, that dihydropyridine calcium antagonists stimulate NO formation in cells in culture (Ding and Vaziri, 1998). In hypertensive rats, chronic treatment with calcium antagonists, however, does improve endothelial function in resistance arteries (Dohi *et al.*, 1994; Tschudi *et al.*, 1994b; Moreau *et al.*, 1995; Takase *et al.*, 1996). Because this beneficial effect is also present in L-NAME-induced hypertension, where the synthesis of NO is still blocked, an alternative NO pathway must be involved (Takase *et al.*, 1996), most likely an enhanced production of EDHF.

Angiotensin-Converting Enzyme Inhibitors

The renin-angiotensin system and endothelium-derived substances are important regulators of the microcirculation. Angiotensin-converting enzyme (ACE), which transforms angiotensin I into angiotensin II, is expressed on endothelial cell membrane (Fig. 5) (Ng and Vane, 1967). ACE is identical to kinase II, which inactivates bradykinin, a potent stimulator of the L-arginine and cyclooxygenase pathways (Vanhoutte *et al.*, 1993). Therefore, ACE inhibitors not only prevent the formation of angiotensin II but also increase the local concentration of bradykinin and in turn increase the production of NO, EDHF, and prostacyclin through B_2 receptors (Wiemer *et al.*, 1991; Yang *et al.*, 1993; Meyer *et al.*, 1995).

Figure 5 A renin-angiotensin system exists on the endothelial cell membrane, which provides locally produced Ang II from Ang I via angiotensin-converting enzyme (ACE). Ang I, angiotensin I; Bk, bradykinin. The relaxing factors (right) include nitric oxide (NO), and endothelium-derived hyperpolarizing factor (EDHF). NO and PGI_2 cause not only relaxation but also inhibition of platelet function.

The decreased breakdown of bradykinin could therefore explain improved endothelial function (Vanhoutte *et al.*, 1993; Tschudi *et al.*, 1994b; Takase *et al.*, 1996) and also normalization of vascular remodeling with ACE inhibitors in small resistance arteries of hypertensive rats (Deng and Schiffrin, 1993; Moreau *et al.*, 1995) as well as in subcutaneous resistance arteries of hypertensive patients (Schiffrin and Deng, 1995).

Endothelin Antagonists

Endothelial dysfunction seen in salt-sensitive hypertension is normalized by ET_A receptor blockade (Fig. 6) (d'Uscio *et al.*, 1997). This suggests that improvement of endothelium-dependent relaxation is mediated in large part via selective activation of ET_B receptors, which in turn stimulates the release of NO and/or prostacyclin, while combined blockade of ET_A/ET_B receptors does not affect endothelial function (Li *et al.*, 1994). This is in line with a study showing that selective blockade of the ET_A receptors increases endogenous NO generation (Verhaar *et al.*, 1998). ET_A receptor antagonists are also able to lower systolic blood pressure and to prevent hypertrophic remodeling (d'Uscio *et al.*, 1997; Matsumura *et al.*, 1999). Thus, functional and structural vascular changes in hypertension are mediated, at least in part, by endogenous ET-1 through activation of ET_A receptors.

As described earlier, the production of ET-1 is enhanced in hypercholesterolemia and atherosclerosis. Previous observations showed that selective blockade of ET_A receptors reduces the formation of fatty streak formation in cholesterol-fed hamsters (Kowala *et al.*, 1995). Interestingly, concomitant administration of an ET_A receptor antagonist inhibits vascular lesion formation and normalizes NO-mediated endothelium-dependent relaxations of the aorta in apolipoprotein E-deficient mice, an animal model of human atherosclerosis (Barton *et al.*, 1998). In addition, epicardial atherosclerosis in humans is associated with impaired endothelium-dependent relaxations in the coronary resistance arteries, indicating that the pathophysiological consequences of atherosclerosis may extend into the microcirculation (Zeicher *et al.*, 1991b). Another study shows that blockade of ET_A receptors normalizes functional changes of small resistance arteries in atherosclerotic apoE-deficient mice (d'Uscio *et al.*, 1998).

Lipid-Lowering Drugs

Plasma cholesterol concentrations play a pivotal role in the development and therapy of hypercholesterolemia and atherosclerosis. Studies have demonstrated that lowering of plasma cholesterol levels has beneficial effects on endothelial function, suggesting that plasma cholesterol is indeed an important factor determining endothelial dysfunction (Anderson *et al.*, 1995; Goode and Heagerty, 1995). It is of most interest that reduced endothelium-dependent relaxations also occur in the microcirculation of patients with hyperlipidemia (Stroes *et al.*, 1995). The mechanisms by which cholesterol-lowering therapy influences vascular changes may involve

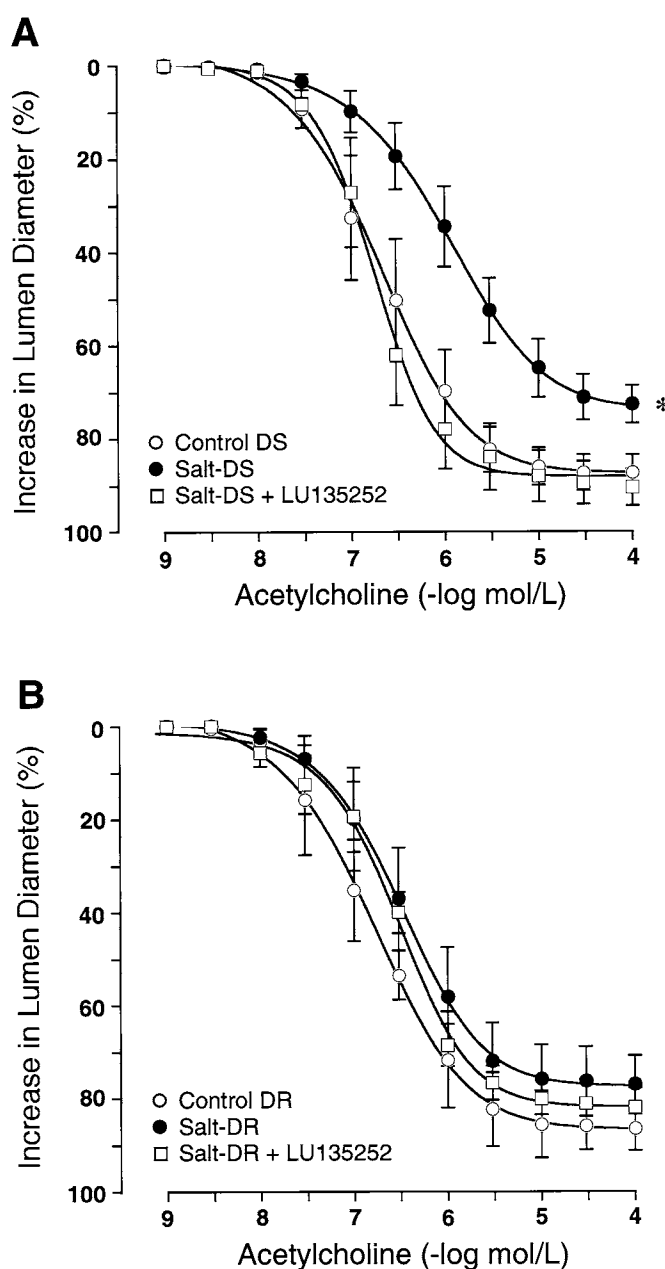

Figure 6 Endothelium-dependent relaxations to acetylcholine of mesenteric resistance arteries in Dahl salt-sensitive (A) and Dahl salt-resistant (B) rats. Results are shown as means \pm SEM ($n = 6$ or 7 per group), and relaxations are expressed as percent of the increase in intraluminal diameter from precontraction with norepinephrine. LU135252: ET_A -receptor antagonist. * $p < 0.05$ versus control for maximal response (ANOVA + Bonferroni). improvement of the NO pathway (Hernandez-Perera *et al.*, 1998). Indeed, statins are able to prevent the inhibitory action exerted by oxidized LDL on endothelial NOS mRNA and protein levels. Thus, these drugs may influence vascular tone of the microcirculation by modulating the expression of endothelium-derived NO. Impaired endothelial function in the microcirculation may contribute to ischemia occurring

under these conditions and in turn may also be important for prognosis of these patients.

Conclusion

NO contributes to the maintenance of vascular tone and structure, by itself and through interactions with cyclooxygenase-derived products and endothelin, in both the endothelium and VSMC. The relative activation and potency of these mediators and their interaction determine the vascular response. In aging, hypertension, hypercholesterolemia, and atherosclerosis, an endothelial dysfunction occurs that is related to an imbalance of endothelial mediators and their action. Some commonly used therapeutic agents such as ACE inhibitors, statins, and possibly ET antagonists seem to have favorable effects on the endothelial function by increasing release and bioavailability of NO.

Activation of NOS by Ca^{2+} -Dependent and Ca^{2+} -Independent Mechanisms

Ingrid Fleming and Rudi Busse

Institut für Kardiovaskuläre Physiologie, Klinikum der JWG-Universität, Frankfurt, Germany

THE NITRIC OXIDE SYNTHASES (NOS) ARE MULTIDOMAIN ENZYMES CONSISTING OF AN N-TERMINAL OXYGENASE DOMAIN THAT CONTAINS BINDING SITES FOR HEME, L-ARGININE, AND TETRAHYDROBIOPTERIN (H_4B), AND A REDUCTASE DOMAIN WITH BINDING SITES FOR NADPH, FMN, FAD, AND CALMODULIN (CAM) (FIG. 1). DURING THE SYNTHESIS OF NITRIC OXIDE (NO), NADPH-DERIVED ELECTRONS PASS TO FLAVINS IN THE REDUCTASE DOMAIN AND MUST THEN BE TRANSFERRED TO THE HEME LOCATED IN THE OXYGENASE DOMAIN, SO THAT THE HEME IRON CAN BIND O_2 AND CATALYZE THE STEPWISE SYNTHESIS OF NO FROM L-ARGININE. THE ASSOCIATION OF CAM WITH ITS BINDING SITE IS GENERALLY ACCEPTED TO ACTIVATE NO SYNTHESIS BY ENABLING THE REDUCTASE DOMAIN TO TRANSFER ELECTRONS TO THE OXYGENASE DOMAIN.

Neuronal NOS

Cellular Expression of nNOS

Neuronal NOS (nNOS) was first characterized in, and purified from, rat and porcine cerebellum. Since then, nNOS has been found to have a widespread distribution in specific neurons of the central and peripheral nervous systems. nNOS is likely to play an important role not only in physiological neuronal functions such as neurotransmitter release, neural development, regeneration, synaptic plasticity, and regulation of gene expression but also in a variety of neurological disorders in which excessive production of NO leads to neural injury. However, nNOS expression is not confined to neuronal cells. In various species, nNOS mRNA transcripts and protein have been detected in nonneuronal cell types including skeletal muscle, macula densa cells, myometrium, and certain vascular smooth muscle cells.

The subcellular localization of nNOS protein varies greatly among the cell types studied. In neurons, both soluble and particulate nNOS protein is found. In skeletal muscle, nNOS protein is mostly particulate, a phenomenon attributed to the PDZ/GLGF motif found within the NH_2 -terminal sequence of the nNOS protein. This motif participates in protein–protein interactions with several other membrane-associated proteins. In neurons, synaptic association of nNOS is mediated by the binding of the PDZ/GLGF motif to the postsynaptic density protein PSD-95 and/or to the related PSD-93 protein. *N*-Methyl-D-aspartate (NMDA) receptors are also known to be associated with PSD-95. In fast-twitch skeletal muscle fibers, the muscle-specific isoform (θ nNOS) is attached to the sarcolemma–dystrophin complex via the PDZ/GLGF motif and interacts mainly with α_1 -syntrophin. Recent studies demonstrated a selective loss of sarcolemmal nNOS in mdx mice, which lack endogenous dystrophin. A similar loss of membrane-associated nNOS

Figure 1 Proposed model for an nNOS dimer indicating domain swapping and electron transfer pathway. CaM, calmodulin; H₄B, tetrahydrobiopterin; AL, autoinhibitory loop; \blacklozenge represents the ZnS₄ recently described to be positioned equidistant from the two heme groups and H₄B. (Modified from Fleming and Busse, 1999.)

was seen in Duchenne and in Becker muscular dystrophy, diseases in which the dystrophin gene is mutated.

Physiological and Pathophysiological Role of nNOS

An excessive production of NO can lead to neurotoxicity. NO plays a role in mediating neurotoxicity associated with a variety of neurologic disorders, including stroke, amyotrophic lateral sclerosis, Parkinson's disease, Alzheimer's disease, Huntington's disease, and HIV dementia. These diseases are associated with partial neuronal depolarization and secondary activation of voltage-dependent NMDA receptors, which results in excitotoxic neuronal cell death (secondary excitotoxicity). Activation of NMDA receptors and the subsequent increase in intracellular Ca²⁺ leads to the activation of Ca²⁺-dependent enzymes, including nNOS.

Ca²⁺/CaM-Dependent NO Production by nNOS

Two phases (early and late phases) of NO production by nNOS have been reported in response to receptor activation. The kinetics of NO production by nNOS in various systems have been reported to mirror changes in intracellular Ca²⁺ level. The rapid phase of nNOS activation is dependent on the release of Ca²⁺ from intracellular stores, whereas the delayed phase is associated with the transmembranous influx of Ca²⁺ and is accompanied by the prolonged formation of NO at functionally effective levels.

How does Ca²⁺ activate NOS? The Ca²⁺-dependent activation mechanism is generally accepted to involve the formation of a Ca²⁺/CaM complex and the association of this complex with the CaM-binding domain situated between the oxygenase and reductase domains. The binding of Ca²⁺/CaM to nNOS is thought to enhance NO production by promoting an intramolecular one-electron transfer between the flavins FAD and FMN.

One similarity with endothelial NOS (eNOS) is that nNOS contains an insert of 40–50 amino acids in the

middle of the FMN-binding domain, which is thought to act as an autoinhibitory loop that disables the enzyme when the physiological concentration of Ca²⁺ within cells is low (Fig. 1). Indeed, activation of the Ca²⁺-dependent NOS isoforms is thought to require the physical displacement of the autoinhibitory peptide so that CaM can access its binding domain. Consistent with the known effect of CaM on electron transfer between FAD and FMN, the autoinhibitory loop regulates nNOS activity by preventing electron transfer from FMN to heme. The situation in the eNOS and nNOS isoforms is not identical, as there is quite a large difference in the basal activity of the two enzymes (nNOS > eNOS). Although there is a high homology between certain sections of the autoinhibitory inserts, in other sections the sequence is markedly different.

REGULATION OF nNOS BY CAVEOLIN

Caveolins associate with and regulate the activity of NOS isoforms, and nNOS interacts with caveolin-3. Caveolin-3 is approximately 60% identical with caveolin-1 and is part of the dystrophin complex. Interactions between nNOS and caveolin-3 appear to be direct and to involve two distinct caveolin scaffolding or inhibitory domains. This interaction is thought to be competitive with CaM, and thus the interaction of nNOS with caveolin-3 inhibits Ca²⁺-dependent enzyme activity. Caveolin may regulate NOS function at more than one level, and the induction of caveolin-3, which may lead to an increased number of caveolae, alters the nNOS–caveolin cycle.

REGULATION OF nNOS ACTIVITY BY LIPIDS

The activity of nNOS has also been proposed to be regulated by interactions with membrane lipids. Phosphatidylinositol 4,5-bisphosphate (PIP₂) and phosphatidic acid (PA) both attenuate L-citrulline production by nNOS, apparently by binding in the vicinity of the CaM-binding domain and interfering with the ability of the enzyme to bind Ca²⁺/CaM. Indeed, both PIP₂ and PA protect the CaM-binding site against trypsin digestion.

REGULATION OF nNOS BY NO

High concentrations of NO inhibit nNOS activity by interacting with the heme prosthetic group. In rat forebrain slices oxygen–glucose deprivation results in a decrease in Ca²⁺-dependent NOS activity and is paralleled by an increase in Ca²⁺-independent cytokine-inducible NOS (iNOS) activity. Both dexamethasone and cycloheximide, which completely inhibit the induction of the Ca²⁺-independent NOS activity, caused a 40–70% recovery in Ca²⁺-dependent NOS activity. Since oxyhemoglobin also produced complete recovery of Ca²⁺-dependent NOS activity, it appears that NO formed after oxygen–glucose deprivation is responsible for this downregulation. Consistently, exposure of nNOS to high concentrations of NO donor agents decreases its activity.

REGULATION OF nNOS BY PHOSPHORYLATION

Both cyclic-GMP-dependent (PKG) and cyclic-AMP-dependent (PKA) protein kinases phosphorylate nNOS on a

single serine residue. The consequence of the phosphorylation of nNOS is a decrease in the catalytic activity of the enzyme. When phosphorylation occurs within the 26-amino acid residue CaM-binding domain of nNOS, the binding of CaM is blocked, suggesting that phosphorylation of the CaM-binding domain of nNOS could be a negative feedback loop to turn off nNOS activity. Indeed, the V_{\max} of the Ser-847 phosphorylated recombinant wild-type nNOS is less than the nonphosphorylated form. Purified recombinant nNOS can also be phosphorylated *in vitro* on Ser-847 by Ca^{2+} /CaM-dependent protein kinases (CaM kinases), including CaM kinase I α (CaM-KI α), CaM kinase II α (CaM-KII α), and CaM kinase IV (CaM-KIV).

Activation of protein kinase C (PKC) in rat cerebellar slices enhances the calcium sensitivity of nNOS. However, in the latter experiments no apparent phosphorylation of nNOS could be detected, despite the fact that PKC can phosphorylate partially purified nNOS *in vitro* and increase enzyme activity. Such data indicate that nNOS is not susceptible to PKC-dependent phosphorylation in cerebellar slices. They also indicate that the PKC-mediated alteration in nNOS activity is related not to direct phosphorylation of the enzyme but rather to the phosphorylation of unknown proteins that regulate the Ca^{2+} sensitivity of nNOS in the cerebellum. The apparent insensitivity of nNOS to PKC-mediated phosphorylation *in situ* may be explained by the finding that PKC preferentially phosphorylates the non- H_4B -stabilized nNOS dimer, and H_4B -dependent dimer stabilization prevents nNOS from PKC-dependent phosphorylation *in vitro*.

nNOS can also be phosphorylated on tyrosine residues. For example, in human astrocytoma T67 cells the enzyme is basally tyrosine phosphorylated, and the tyrosine phosphatase inhibitor vanadate increases nNOS phosphorylation and decreases NO production. Tyrosine kinase inhibitors, on the other hand, reduce the tyrosine phosphorylation of nNOS and enhance enzyme activity. However, no information on the site of nNOS tyrosine phosphorylation has been provided.

Not only the phosphorylation of nNOS, but also that of CaM determine enzyme activity. CaM is known to be constitutively phosphorylated, and the binding of phosphorylated CaM to nNOS increases its V_{\max} by approximately 2.6-fold with respect to that of the nonphosphorylated CaM:nNOS. Phosphorylation of CaM has very little effect on binding of calcium to the enzyme despite the fact that the two main phosphorylated amino acids Ser-101 and Tyr-99 are located in the third calcium-binding loop of CaM.

Inducible NOS

Inflammatory mediators such as interleukin-1 β and tumor necrosis factor- α induce the formation of NO in vascular cells as well as in many other types of mammalian cells such as hepatocytes, chondrocytes and cardiomyocytes. The cytokine-inducible NOS isoform iNOS is generally thought to be unregulated by any cellular signaling processes other

than those that determine its expression and/or degradation. Thus, from the moment of dimer formation to the moment of dimer disruption, this enzyme produces excessive amounts of NO.

Ca^{2+} -Independent NO Production by iNOS Activation

The iNOS isoform is to all intents and purposes a Ca^{2+} -independent enzyme, even though this statement is not strictly speaking true. Indeed, although iNOS is fully active at basal $[\text{Ca}^{2+}]_i$ and although increases in cellular Ca^{2+} cannot further enhance the production of NO, the activity of iNOS can be completely inhibited in the presence of EDTA and EGTA, just as for the other NOS isoforms.

What accounts for the differential sensitivity of iNOS to physiological concentrations of Ca^{2+} , and why, once expressed, is this enzyme fully active? The difference may well be attributable to the fact that this NOS isoform does not contain the autoinhibitory peptide insert found within the so-called Ca^{2+} -regulated isoforms (which is thought to restrict access to the CaM-binding domain). Indeed, whereas the binding of CaM to eNOS and nNOS is generally described as Ca^{2+} -dependent and reversible, the binding of calmodulin to iNOS is Ca^{2+} -independent and irreversible. The introduction of the eNOS CaM-binding domain into iNOS has been shown to render the inducible enzyme Ca^{2+} /CaM dependent, whereas the deletion of this sequence in eNOS results in a CaM-independent enzyme. However, although the deletion of the autoinhibitory peptide sequence from nNOS results in a less Ca^{2+} -sensitive isoform, the introduction of the autoinhibitory loop peptide into iNOS only slightly modifies its enzymatic properties, and a significant Ca^{2+} -independent enzyme activity is retained. Therefore, the presence of the autoinhibitory loop may only partly determine the Ca^{2+} sensitivity of the three NOS isoforms, and evidence exists to suggest that the CaM which is so tightly bound to iNOS interacts with two domains, the first being the CaM-binding domain and the second appearing to be contained within the flavoprotein domain.

Other Modulators of iNOS Function

THE INTERACTION OF iNOS WITH CAVEOLIN

Unlike the other NOS isoforms, the activity of iNOS is not thought to be dependent on its subcellular localization, and the enzyme is generally assumed to be distributed throughout the cell cytosol. Evidence exists for the localization of iNOS in the cytoplasm, perinuclear space, Golgi complex, mitochondria, plasma membrane, and along contractile fibers of cardiomyocytes, as well as for the appearance of iNOS staining of the cell nuclei in the course of cultivation. The residues in eNOS that bind to caveolin-1 and -3 are conserved in iNOS, and there is some structural evidence to suggest that caveolin binding to the reductase domain of iNOS inhibits the transfer of electrons to heme. Scaffolding domain peptides derived from caveolin-1 and caveolin-3 inhibit iNOS activity *in vitro*. However, it is not

entirely clear whether caveolin is actually involved in the physiological regulation of iNOS-mediated NO production, as iNOS and the caveolins do not necessarily come into close contact *in vivo*.

REGULATION OF iNOS BY PHOSPHORYLATION

Although numerous investigations into the role of various kinases in the induction of iNOS have been performed, almost nothing is known about the acute regulation of iNOS activity by phosphorylation. iNOS does appear to be phosphorylated on serine and tyrosine residues. In macrophages, iNOS protein can be phosphorylated via a phosphatidylinositol 3-kinase-independent but FKBP12-rapamycin-associated protein-dependent pathway, although no information regarding the specific amino acid residue phosphorylated is currently available. A little more is known about the tyrosine phosphorylation of iNOS. This is thought to be an early event coinciding with the appearance of newly synthesized iNOS. The tyrosine phosphorylation of iNOS is, as expected, enhanced by the protein tyrosine phosphatase inhibitor vanadate, which also increases iNOS activity.

Endothelial NOS

The functional eNOS, like the other isoforms, is a dimer composed of two identical subunits, both of which are myristoylated and palmitoylated. H₄B may well prove to be essential for the dimerization of eNOS, and only the dimer retains the ability to bind substrate and cofactors. Maintenance of the integrity of the H₄B-binding site on the eNOS oxygenase domain appears to involve a zinc tetrathiolate or Zn[S-cysteine]₄, positioned equidistant from each heme and H₄B. The identification of ZnS₄ in eNOS may well be of physiological relevance. It is feasible that increasing nitrosative stress *in vivo* may result in the release of the zinc from the oxygenase domain, may destabilize the H₄B, and/or may deplete eNOS of this essential cofactor while favoring the generation of superoxide anion (O₂⁻).

Comparative analysis of NOS domain interactions shows that subunit association of NOS may involve head-to-tail interactions between the oxygenase and reductase domains. In order to properly align reductase and oxygenase domains for NO synthesis, electrons are transferred from the flavin to heme of adjacent subunits.

Ca²⁺-Dependent eNOS Activation

Until recently, regulation of the constitutive NOS in endothelial cells was attributed solely to changes in endothelial [Ca²⁺]_i. Indeed, the increase in endothelial NO production elicited by endothelial agonists, such as bradykinin and acetylcholine, mirrors endothelial [Ca²⁺]_i (Fig. 2) and has been demonstrated to be strictly dependent on the formation of a Ca²⁺/CaM complex. Unstimulated endothelial cells continuously produce NO, suggesting that the intracellular Ca²⁺

Figure 2 Temporal relationship between the agonist (bradykinin)-induced increase in endothelial concentration of free Ca²⁺ ([Ca²⁺]_i) and the production of NO assessed as the activity of the intracellular NO receptor the soluble guanylyl cyclase (sGC).

level under resting conditions is just sufficient to allow the NOS to turn over and produce low amounts of NO.

THE INTERACTION OF eNOS WITH CALMODULIN

The identification of a CaM-binding domain in the primary structure of eNOS together with the finding that CaM-binding proteins inhibited enzyme activity suggested that the binding of a Ca²⁺/CaM complex is essential to activate the constitutive enzyme.

Alterations in the CaM-binding domain determine the Ca²⁺ sensitivity of the various NOS isoforms, and substitution of eNOS and iNOS CaM-binding domains in eNOS-iNOS chimeric proteins produces major alterations in the Ca²⁺/CaM dependence of the intact enzymes (see earlier). The CaM-binding domain of eNOS has also been reported to directly bind phospholipids, and thus it may determine the membrane association of the enzyme. Both a direct physical interaction and an association dependent on the phosphorylation of both the CaM-binding domain of eNOS and CaM have been proposed.

The most distinctive difference between the Ca²⁺-regulated and Ca²⁺-independent NOS isoforms is the existence of the polypeptide insert (40–50 amino acids) in the FMN-binding domains of the Ca²⁺-dependent enzymes. Three-dimensional molecular modeling suggested that the insert originates from

a site immediately adjacent to the CaM-binding sequence, and synthetic peptides derived from the 45-amino acid insert were found to potently inhibit the binding of CaM to eNOS as well as enzyme activity. On the basis of these observations, it was suggested that the polypeptide insert is an autoinhibitory control element, which physically impedes CaM binding and thus enzyme activation. Such a control mechanism would imply that Ca^{2+} /CaM must displace the insert on binding to eNOS. This hypothesis is supported by the fact that the concentration of Ca^{2+} that is required to activate eNOS is markedly reduced following deletion of the autoinhibitory loop, and maximal enzyme activity is significantly (up to fourfold) enhanced. The autoinhibitory sequences in the two Ca^{2+} -dependent isoforms are not identical, and since the basal activity of nNOS is greater than that of eNOS, it is assumed that the eNOS inhibitory sequence is a much more effective inhibitor of enzyme activity. Indeed, synthetic peptides derived from the eNOS insertion sequence proved to be much more effective inhibitors of eNOS and nNOS activity than comparable peptides based on the nNOS insert. It is currently thought that the autoinhibitory loop regulates eNOS activity via at least two mechanisms, one related to the Ca^{2+} -dependent binding of CaM to the CaM-binding domain and the second to a constant partial inhibition of reductase activity.

The insert peptide is also a potential site for phosphorylation (12 of the 45 amino acids are either serine or threonine) and contains recognition motifs for PKC and casein kinase II. Therefore, phosphorylation and/or dephosphorylation may influence the affinity of insert peptides for binding and thus the sensitivity and/or affinity of eNOS/CaM binding.

THE INTERACTION OF eNOS WITH CAVEOLIN-1

The subcellular localization of eNOS and alterations in its cellular compartmentalization following cell stimulation are controversial. Previous reports have assigned eNOS to the Golgi apparatus, whereas others have localized eNOS in plasma membranes or partially or exclusively in plasmalemmal caveolae. The truth lies somewhere in between, as immunostaining of porcine coronary arteries for eNOS reveals an association with the plasma membrane and with a perinuclear region, identified as the Golgi apparatus. Moreover, costaining of endothelial cells with antibodies raised against eNOS and caveolin-1 shows that not all eNOS is colocalized with caveolin-1, and a significant proportion of eNOS can be found within cell-cell contacts. In which fraction eNOS is active in unstimulated cells and can account for the basal production of NO is also controversial, since the eNOS in caveolae is thought to be mostly inactive (see below), and disruption of the Golgi apparatus in intact arterial segments reportedly fails to affect NO-mediated relaxation.

The binding of caveolin-1 to a consensus site ($\text{F}^{350}\text{XAAPFXXW}$) in the eNOS oxygenase domain is proposed to antagonize CaM binding and thereby inhibit enzyme activity. This motif in eNOS lies between the heme and the CaM-binding domain adjacent to a glutamate residue

that is necessary for the binding of L-arginine, suggesting that caveolin-1 may interfere with the reduction of heme iron. Analysis of the crystal structure of the eNOS oxygenase domain revealed that the putative caveolin-1 recognition motif is primarily inaccessible to solvent. Therefore, it is relatively unlikely that caveolin-1 is able to interact with this sequence. Other groups have, however, detected interaction between both the N- and C-terminal domains of caveolin-1 and the oxygenase domain of eNOS. In experiments to examine how a caveolin-1 scaffolding domain peptide (amino acids 82–101) would affect NO synthesis, it was demonstrated that caveolin-1 must bind to the reductase domain of eNOS in order to inhibit enzyme activity. Therefore, caveolin-1 binding to the reductase domain of eNOS compromises its ability to bind CaM and to donate electrons to the heme subunit, thereby inhibiting NO synthesis. The interaction of caveolin-1 with the reductase domain was independent of the caveolin binding motif and was reversed by CaM. Coexpression of eNOS and caveolin-1 leads to a marked inhibition of enzyme activity. This inhibitory interaction is reported to be reversed by the addition of CaM, suggesting that eNOS activity may be determined by the relative proportion of eNOS- Ca^{2+} /CaM to eNOS-caveolin-1-binding.

One additional posttranslational mechanism thought to govern the interaction between eNOS and caveolin-1 is tyrosine phosphorylation, although it is not clear at the moment whether or not one or both of the proteins must be tyrosine phosphorylated.

Although there is overwhelming biochemical evidence for the existence of such a reversible protein-protein interaction, the extent of the eNOS-caveolin-1 interaction *in vivo* is still uncertain. For example, caveolae contain relatively large concentrations of CaM, and whether the stoichiometry of CaM to caveolin-1 in the vicinity of eNOS could ever reach the state at which eNOS is mostly inhibited is, at the moment, unclear. Moreover, the ongoing debate regarding the competitive antagonistic roles of CaM and caveolin-1 undermines the possible relevance of the autoinhibitory loop in the vicinity of the CaM-binding domain in regulating eNOS function.

What happens to eNOS after dissociation from the caveolin-1 complex is also largely unresolved. Although the dissociation of eNOS from a membrane fraction and its translocation to the cytosol following cell stimulation with bradykinin has been described, this finding is very controversial.

At this stage it should be stressed that although the points discussed earlier are applicable to the endothelium on the whole, the endothelium of one vessel or vascular bed is not always identical with that of another. The intracellular localization of eNOS differs in endothelial cells within one organ, as do the specific proteins expressed by the endothelium from one organ to the next.

OTHER MODULATORS OF eNOS FUNCTION

There is a clear disparity in the temporal relationship between agonist-induced increases in endothelial $[\text{Ca}^{2+}]_i$ and the activation of eNOS, with the duration of the Ca^{2+} re-

sponse being significantly shorter than that of the subsequent NO production. Indeed, apart from changes in intracellular levels of Ca^{2+} , a number of posttranslational mechanisms have been proposed to regulate eNOS activity, including the interaction of eNOS with associated proteins, interaction with membrane phospholipids, and phosphorylation. In addition, relatively small pH changes in the physiological range (from pH 6.7 to pH 7.4) markedly alter the activity of the eNOS. High concentrations of NO may also affect eNOS activity by interacting with the heme prosthetic group, and the acute withdrawal of inhaled NO is associated with an increase in pulmonary vascular resistance.

Associated Proteins The concept that eNOS may complex proteins which determine cellular targeting or regulate its activity is somewhat analogous to the situation described for nNOS, which associates with $\alpha 1$ -syntrophin, the postsynaptic density proteins (PSD-95 and PSD-93).

ENAP-1 ENAP-1 (endothelial NOS-associated protein-1) is a tyrosine-phosphorylated, approximately 90-kDa protein observed to interact with eNOS immunoprecipitated from cultured bovine aortic endothelial cells. The Ca^{2+} -elevating, receptor-dependent agonist bradykinin is reported to induce the association of ENAP-1 with eNOS, but the functional significance of this remains to be elucidated.

Hsp90 Heat-shock proteins (Hsp100, Hsp90, Hsp70, Hsp60, and the small Hsp/ α -crystallins), so called because they are preferentially synthesized by organisms exposed to heat or other physiological stresses, are also expressed constitutively and function as molecular chaperones, able to mediate many cellular processes by influencing higher order protein structure and acting as a scaffolding protein. Several signal transduction systems, especially steroid receptors, utilize an interaction with Hsp90 as an essential component of the signaling pathway. A number of signaling molecules such as G-protein $\beta\gamma$ subunits and protein kinases, including Src and Raf components of the mitogen-activated protein kinase (MAP) cascade, are also bound to Hsp90. Geldanamycin and herbimycin, commonly accepted as inhibitors of the Src family of tyrosine kinases, do not inhibit the kinase activity of Src but bind in a specific manner to Hsp90, inhibiting Src–Hsp90 heterocomplex formation and increasing Src turnover.

Hsp90 has been identified as an eNOS-associated protein, and its binding to the enzyme increases catalytic activity. A certain amount of Hsp90 appears to complex with eNOS in unstimulated endothelial cells, as immunoprecipitation of Hsp90 results in the recovery of eNOS, and vice versa. In response to cell stimulation with histamine or vascular endothelial growth factor (VEGF), Hsp90 is associated with eNOS, and exposure of endothelial cells to fluid shear stress stimulates the association of both proteins, albeit with a slower time course. In all cases the association of Hsp90 with eNOS increased NO production and was prevented by pretreatment with geldanamycin. The eNOS-associated Hsp90 may also serve as a scaffolding protein, facilitating the organization of additional associated regulatory proteins.

Given the similarity in the molecular weight of ENAP and Hsp90, it is possible that these are one and the same protein. Although Hsp90 has been described as a serine/threonine phosphorylated protein, coimmunoprecipitation experiments showed that the tyrosine kinase inhibitor genistein inhibited ligand-induced release of Hsp90 from the glucocorticoid receptor. Thus, the interaction of proteins with Hsp90 may also be regulated by a tyrosine kinase-dependent pathway. Preliminary reports also indicate that the Hsp90 which forms a complex with eNOS following the application of fluid shear stress is indeed tyrosine phosphorylated.

Phosphorylation The role of protein kinases in the regulation of endothelial NO production is a topic of intense current investigation, because several consensus sequence sites for phosphorylation by PKA, Akt/PKB (see later), PKC, and CaM kinase II (CaM-KII) are found in eNOS (Fig. 3). Although eNOS was initially reported to be basally phosphorylated solely on serine residues, it is now clear that eNOS is also phosphorylated on threonine and tyrosine residues. Whereas some progress has been made in elucidating the kinases that phosphorylate eNOS on serine and threonine residues, the amino acids they phosphorylate, and the consequences of phosphorylation on enzyme activity, elaborating the functional consequences of eNOS tyrosine phosphorylation is extremely complex, as this modification is only evident in endothelial cells *in situ* or in primary cultured cells.

PKC In cultured endothelial cells, the Ca^{2+} -elevating receptor-dependent agonist bradykinin was initially described to enhance the serine phosphorylation of eNOS, an effect which was maximal after 5 min and was maintained for at least 20 min. This bradykinin-induced phosphorylation of eNOS appears to be a Ca^{2+} -dependent phenomenon and is inhibited either by a calmodulin antagonist or by the removal of extracellular Ca^{2+} . A rough comparison of the time course of NO production and eNOS activation in response to bradykinin suggests that at least this serine phosphorylation of eNOS may be an inactivating mechanism and fits well with the observations that PKC (which phosphorylates eNOS *in vitro*) negatively regulates endothelial NO production. In addition, the exposure of pulmonary artery endothelial cells to sodium nitroprusside (SNP) enhances the serine phosphorylation of eNOS in a PKC-dependent manner and attenuates eNOS activity. PKC inhibitors significantly enhance agonist-induced NO release. However, the serine residue phosphorylated by PKC is unknown.

AMPK The AMP-activated protein kinase (AMPK) can be categorized equally well under the heading NOS-associated protein as under the heading eNOS kinase. This rather unusual kinase is part of a family generally described as “metabolite sensing kinases” that are activated following heat shock, vigorous exercise, hypoxia/ischemia, and starvation. Initially, AMPK was thought to be an indicator of intracellular energy demands, but it also appears to modulate intracellular energy levels, as it initiates changes to maintain intracellular ATP levels and prevent complete ATP deple-

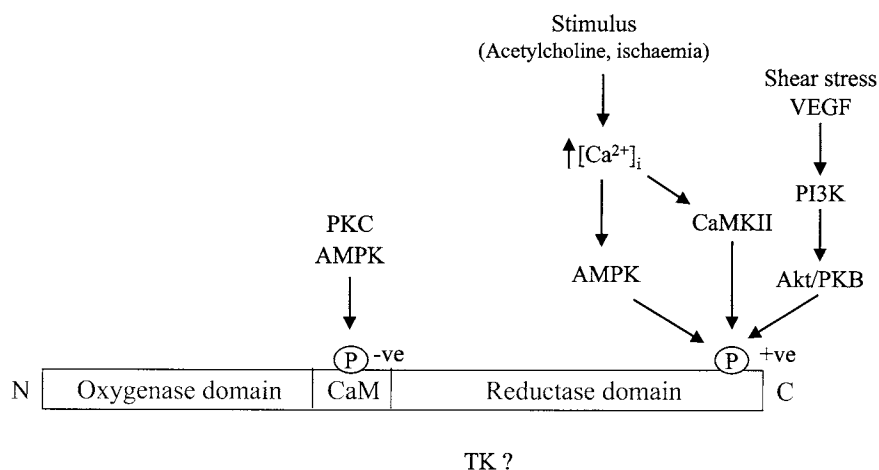

Figure 3 Regulation of eNOS phosphorylation and activity by different stimuli. Stimuli that elevate endothelial Ca^{2+} levels activate AMP-activated protein kinase (AMPK) and CaM-dependent kinase II (CaM-KII) to phosphorylate Ser-1177 and enhance NO production. Phosphorylation of the same residue is achieved in the absence of an increase in endothelial Ca^{2+} following stimulation with mechanical stimuli (such as shear stress) as a consequence of the sequential activation of phosphatidylinositol 3-kinase (PI3K) and Akt/PKB. eNOS appears to be basally phosphorylated by both AMPK and PKC on Thr-495. This residue is situated within the CaM-binding domain, and thus inhibits enzyme activity by interfering with the association of CaM with eNOS. (Modified from Michell *et al.*, 1999.)

tion; that is, once activated the enzyme switches off ATP-consuming anabolic pathways and switches on ATP-producing catabolic pathways. Functionally, the activity spectrum of AMPK has not been fully elucidated, but AMPK is clearly a multisubstrate enzyme.

What has a kinase that regulates the cellular ATP balance to do with the regulation of eNOS? This is actually quite a complicated process as, depending on the cellular conditions, AMPK can activate or inactivate eNOS. Fitting with the known role of AMPK as a metabolite sensor, the interaction between eNOS and AMPK was first demonstrated in rat hearts in response to ischemia. AMPK coprecipitates with eNOS from cardiac homogenates as well as the eNOS isolated from endothelial cells of different origins. Activation of AMPK in the presence of Ca^{2+} /CaM following the induction of ischemia results in the serine phosphorylation of eNOS and its activation. The serine residue phosphorylated by AMPK is Ser-1177, which is located in the carboxyl-terminal region of the reductase domain.

Although various forms of metabolic stress are expected to activate eNOS via its AMPK-dependent phosphorylation, the full spectrum of physiological stimuli resulting in the activation of AMPK and the AMPK-dependent phosphorylation of eNOS in endothelial cells remains to be fully elucidated.

Ca^{2+} -Independent eNOS Activation

Although classified as a Ca^{2+} /CaM-dependent enzyme, a basal eNOS activity was originally reported at Ca^{2+} concentrations as low as 10 nM in lysates prepared from native endothelial cells, indicating that a significant portion of the NO produced by unstimulated endothelial cells may be

formed via a Ca^{2+} -independent pathway. Little physiological relevance was attributed to this phenomenon, especially after the identification of a CaM-binding domain in the primary structure of eNOS. More recent thorough biochemical studies have, however, reinforced the original observation that eNOS may produce NO in an apparently Ca^{2+} -independent manner. Although eNOS, like the neuronal isoform, requires the binding of Ca^{2+} /CaM to achieve maximal activity, a basal level of NO production can be demonstrated when Ca^{2+} /CaM is omitted and 0.5 mM EDTA is present in the assay solution. Moreover, eNOS binds CaM so tightly that the activity of the purified enzyme is about 80% of maximum, and immunoprecipitation of eNOS results in the coprecipitation of CaM, unless stringent washing procedures are used.

Experimental evidence has demonstrated that a number of stimuli can activate eNOS in an apparently Ca^{2+} -independent manner; that is, NO production can be elicited in the absence of an increase in intracellular Ca^{2+} , and/or in the presence of an intracellular Ca^{2+} chelator. These stimuli include mainly physical stimuli, such as shear stress and isometric stretch, as well as growth factors and hormones such as VEGF and estrogen. It is important to stress, however, that although there are obviously two completely separate pathways that can lead to the activation of eNOS, both are, strictly speaking, Ca^{2+} dependent, as eNOS activity (like that of iNOS) is abolished in the presence of high concentrations of EDTA and EGTA.

Fluid Shear Stress, Stretch, and Strain

Blood flow through a vascular segment generates a viscous drag at the luminal surface of endothelial cells that can

be expressed as shear stress (τ) and can be calculated according to Poiseuille's law (see Fig. 4). This relation highlights the fact that relatively small decreases in vessel diameter at constant flow can markedly increase shear stress at the endothelial surface. It should be noted, however, that shear stress is calculated under the assumption that the flow profile is parabolic, a situation which is never realized *in vivo* owing to the pulsatile nature of blood flow and the fact that blood vessels are distensible. Branching and bifurcations along the vascular tree together with a gradual decrease in diameter also disfavor the establishment of a stable flow profile.

Although it is sometimes assumed that pressure per se is a proper physiological stimulus for the vascular wall, it must be emphasized that the application of pressure in the physiological range (below 1 atm) to a tissue which is essentially incompressible due to its high water content has no direct effect on cell function. Rather, the pressure exerted on a compliant, anisotropic tissue elicits deformation, that is, distension (stretch). As a result of pulsatile pressure changes and the anisotropy of the tissue, cells within the vascular wall are subjected to three-dimensional cyclic strain in the radial, longitudinal, and circumferential directions.

There are also hemodynamically relevant cell-cell-generated forces that cannot be expressed by a simple physical relationship. One example is the isometric contraction, in which the development of contractile force within the smooth muscle cell layer counteracts the distending transmural pressure. Under such conditions there is a relative displacement of opposing cell layers within the vascular

wall (e.g., smooth muscle cells versus elastic lamina and endothelial cells), despite the fact that no net movement occurs. Although the displacement induced may be subtle, the close physical arrangement of endothelial focal adhesion contacts and the smooth muscle suggests that the forces developed at the abluminal surface of endothelial cells may be greater than those generated by shear stress on the luminal surface.

In principle, the relative contribution of pulsatile stretch and wall shear stress to the adjustment of local vascular tone is likely to depend on a number of factors including vessel architecture, moment-to-moment changes in smooth muscle activity, and the ability of endothelial and smooth muscle cells to sense hemodynamic stimuli and to produce vasoactive factors. During each cardiac cycle, the ventricles eject a given volume of blood into the aorta and the pulmonary artery. At each site in the vasculature through which this pulse wave travels, three basic wave phenomena can be observed: a pressure pulse, a flow pulse, and a volume pulse (which is a change in cross-sectional area). In an artery *in situ*, two extreme situations that result in an increase in either shear stress or circumferential strain at a given pulse pressure are conceivable; in other words, in a vessel exhibiting high tone and thus low distensibility, the endothelium would be exposed to shear stress levels greatly elevated above those observed in a highly distensible vessel with low tone. The converse is, of course, the case for circumferential strain or stretch.

However, although it is tempting to break down hemodynamically generated forces into singular physical compo-

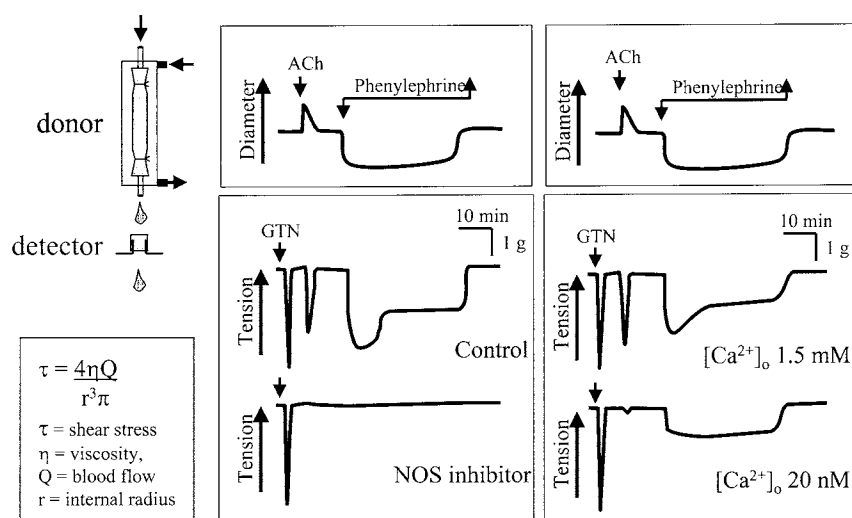

Figure 4 Bioassay system for the detection of NO released from endothelium-intact rabbit iliac artery segments. The upper tracing represents the change in external diameter of the endothelium-intact donor segment following the bolus application of acetylcholine (ACh) and superfusion with phenylephrine to contract the artery and thus increase shear stress at constant flow according to Poiseuille's law (insert). The lower traces represent the relaxation of an endothelium-denuded detector ring in response to topical application of glyceryl trinitrate (GTN) or superfusion with the effluent from the donor. The tracings shown demonstrate that the relaxations of the detector ring are completely inhibited by a NOS inhibitor, and that the removal of extracellular Ca^{2+} abolishes the ACh-induced production of NO by the donor segment but not that elicited by an increase in fluid shear stress. (Modified from Ayajiki *et al.*, 1996.)

nents such as circumferential stretch or strain and wall shear stress, it must be stressed that such a procedure is purely theoretical, as changes in pulsatile stretch and shear stress are inextricably linked.

Fluid Shear Stress and Ca^{2+} -Independent NO Production

Endothelial cells are continuously exposed to shear stress, and not to agonists such as acetylcholine or bradykinin, and it is shear stress (together with other mechanical stimuli such as cyclic stretch) that is the physiologically most relevant determinant of endothelial activation, NO production, and, as a consequence, the local regulation of vascular tone and organ perfusion. The first demonstration of an apparently Ca^{2+} -independent eNOS activation in native endothelial cells (i.e., endothelial cells in an isolated intact arterial segment) was in response to fluid shear stress in a classic bioassay system where the NO produced in a perfused, endothelium-intact donor segment was detected by monitoring alterations in the tone of an isometrically contracted endothelium-denuded detector ring (Fig. 4). In this bioassay system, constriction of the donor segment at a constant perfusion rate increases fluid shear stress at the endothelial surface and evokes a pronounced vasodilation in the detector ring. This response consisted of an initial transient peak followed by a stable plateau phase that was maintained as long as the donor remained constricted. The removal of the endothelium from the donor artery, or pretreatment with a NOS inhibitor, abolished both the acetylcholine and the shear stress-induced relaxation of the detector segment.

Replacing the solution perfusing the donor segment with a nominally Ca^{2+} -free solution (i.e., lowering the extracellular Ca^{2+} concentration from 1.6 to ~ 10 nM) completely abolished the acetylcholine-induced release of NO and the peak component of NO release in response to vasoconstriction. The plateau phase of NO release, however, was unaffected by the absence of extracellular Ca^{2+} .

Phosphorylation

As the transmembranous influx of Ca^{2+} does not appear to regulate eNOS activity following the application of fluid shear stress, other intracellular signaling pathways must be involved in the regulation of NO production by eNOS. Because fluid shear stress is known to alter the phosphorylation of numerous endothelial cell proteins, and a similar and apparently Ca^{2+} -independent activation of eNOS can be achieved by incubating endothelial cells with inhibitors of either serine or tyrosine phosphatases, it seemed logical to assume that Ca^{2+} -independent eNOS activity may be modulated by eNOS phosphorylation or by the phosphorylation of an eNOS-regulatory protein.

AKT/PKB

Akt (otherwise known as protein kinase B or PKB) is a downstream target of at least two kinases [the phosphatidy-

linositol 3-kinase (PI3K) and the p38 MAP kinase], and it phosphorylates serine residues within a defined recognition sequence, RXXRXXS. This motif is present in the sequence surrounding R1177Q in eNOS. PI3K and Akt/PKB can be activated by some, but not all, of the stimuli that result in the activation of eNOS. For example, the classic Ca^{2+} -elevating agonists bradykinin, histamine, and Ca^{2+} ionophores do not activate Akt/PKB in arterial endothelial cells, whereas mechanical stimuli, such as fluid shear stress and isometric contraction, and the growth factors VEGF, insulin, and angiopoietin do. In other words, stimuli that elicit the apparently Ca^{2+} -independent activation of eNOS generally also activate Akt/PKB.

In order for an Akt/PKB-mediated phosphorylation of eNOS to be accountable for the alteration in eNOS Ca^{2+} sensitivity, a number of criteria must be fulfilled:

1. Akt/PKB must be rapidly activated following the onset of the stimulus.
2. Activation of Akt/PKB must be maintained as long as the stimulus duration (at least in the case of shear stress).
3. Activation of Akt/PKB should occur independently of the presence of extracellular Ca^{2+} .
4. Akt/PKB should associate with eNOS and phosphorylate it.
5. The Akt/PKB-mediated phosphorylation of eNOS should alter the sensitivity of the enzyme to Ca^{2+} .

All of these criteria are met by Akt/PKB. Therefore, to all intents and purposes, the Ca^{2+} -independent activation of eNOS can be attributed to the activation of PI3K and its downstream target Akt/PKB. Indeed, inhibiting the activation of PI3K prevents the activation of Akt/PKB, the phosphorylation of eNOS Ser-1177, and the shear stress- or VEGF-induced production of NO. Specific mutation of Ser-1177 to aspartate in order to mimic the continuous phosphorylation of the protein significantly augments enzyme activity (Fig. 5). On the other hand, overexpression of a construct in which Ser-1177 phosphorylation was inhibited by replacement with alanine resulted in an enzyme activity that was consistently lower than that of the wild-type enzyme.

There are, however, a number of points that remain to be clarified, the first being how the phosphorylation of Ser-1177 alters the affinity of eNOS for Ca^{2+} . One possibility under investigation is whether phosphorylation increases the affinity of the eNOS reductase domain for CaM. If this is the case, how can the phosphorylation of a serine residue located at the carboxy-terminal reductase domain influence CaM binding? Perhaps the best current hypothesis is that Ser-1177 is part of an additional inhibitory motif that stabilizes the autoinhibitory loop in its "closed position" and thus prevents CaM from obtaining access to its binding domain (Fig. 6). Phosphorylation of Ser-1177 may alleviate this intrinsic inhibition, so that the autoinhibitory loop can be displaced and the CaM present in the vicinity of eNOS is able to bind and enhance eNOS activity. Such a sequence of events, should it be proved correct, is likely to be a general eNOS activation mechanism, as this one residue (Ser-1177) can be phosphorylated by more than one protein kinase. Although

Figure 5 The wild-type (wt) eNOS is less active and markedly more sensitive to alterations in Ca^{2+} concentration than the eNOS phosphomimetic (replacement of Ser-1177 with aspartate). NO activity was assessed as the production of L-[^3H]citrulline from L-[^3H]arginine. (Modified from Dimmeler *et al.*, 1999.)

Akt/PKB currently appears to be the only kinase that can phosphorylate this residue without an increase in intracellular Ca^{2+} , AMPK and CaM kinase are also able to phosphorylate it and enhance NO production in response to other stimuli.

Despite several convincing demonstrations that Akt/PKB directly phosphorylates eNOS *in vitro*, it is possible that other signal transduction pathways must also be activated in

parallel in order to facilitate NO production. For example, insulin and angiopoietin which, as mentioned earlier, are potent activators of Akt/PKB in native and cultured endothelial cells, have little or no effect on NO production. Although few data are available at the moment, it is more than likely that stimulus-induced alterations in the association of eNOS with other signaling or adapter molecules will play a decisive role in the regulation of endothelial NO production.

AMPK

It is no mistake that the AMP-activated kinase appears under two different subheadings, as AMPK does differentially regulate eNOS activity depending on the availability of Ca^{2+} /CaM. AMPK actually phosphorylates eNOS on two distinct sites. The first, as mentioned earlier, is Ser-1177. However, in the absence of Ca^{2+} /CaM, AMPK phosphorylates eNOS on Thr-495. Thr-495 is an amino acid situated within the CaM-binding domain and is also thought to be phosphorylated by PKC. In both cases, phosphorylation, which attenuates enzyme activity, most probably by interfering with the binding of Ca^{2+} /CaM. The stimuli that result in the activation of AMPK and eNOS Thr-495 phosphorylation are completely unknown, as the induction of ischemia, which is a classic activator of AMPK, does not affect the threonine phosphorylation of eNOS.

TYROSINE KINASES

Nonreceptor tyrosine kinases play a central role in endothelial cell signaling and may functionally link rearrangement of the cytoskeleton or focal adhesion points with more

Figure 6 Proposed model for the activation of eNOS and the conferral of apparent Ca^{2+} independence on eNOS by the phosphorylation of Ser-1177. CaM, calmodulin; CBD, CaM-binding domain; AL, autoinhibitory loop; P, phosphorylation. The open circle represents the Akt/PKB recognition motif.

classic signal transduction pathways (see later). Results obtained in the shear stress bioassay suggest a role for tyrosine kinases in mediating shear stress-induced NO production, as tyrosine kinase inhibitors almost completely abolish shear stress-dependent NO production. Indeed, the application of fluid shear stress to cultured endothelial cells results in both transient and maintained alterations in the protein tyrosine phosphorylation of detergent-soluble and -insoluble proteins and has been shown to enhance eNOS tyrosine phosphorylation. The tyrosine residues phosphorylated following the application of shear stress remain to be elucidated, as does the kinase which phosphorylates it.

How Does an Endothelial Cell Sense Physical Stimuli?

The endothelial cell can be viewed as a membrane stretched over a frame composed of microtubules, intermediate filaments, and actin fibers that transverse the cells and appear to end in characteristic adhesion complexes. Even under nonstimulated conditions the entire endothelial cytoskeleton is maintained under tension, and in response to an externally applied stimulus intracellular tension is redistributed over the cytoskeletal network. This tensegrity architecture within cells permits forces to be directly transmitted from the cell surface, through the cytoskeleton, and across physically interconnecting filaments. Thus, extracellular forces are superimposed on preexisting forces within cells attached to the extracellular matrix at focal adhesion points,

and to each other at cell–cell contacts. Generally, signaling molecules are clustered around and inherent to these contact sites, so that it is conceivable that the application of a stress, which is transmitted through the entire cell by the actin cytoskeleton, activates signal transduction cascades without the need of a specific shear stress or stretch receptor (see Fig. 7). Molecular connections between integrins, cytoskeletal filaments, and nuclear scaffolds have been proposed to provide a pathway for signal transfer, thus raising the possibility that mechanical stimuli may be passed on to the nucleus in the absence of or simultaneously with mechanochemical signaling processes.

Focal adhesion sites, cell–cell contacts, and caveolae have been suggested to play a critical role in the differential activation of signaling cascades in response to fluid shear stress. However, rather than there being one major site of shear sensing, it is more than likely that the signaling pathways activated by the mechanical perturbation of endothelial cells are determined by the sites where there is the greatest alteration in force. Thus, the apparent selective regulation of cellular signaling pathways is in fact predetermined by the localization of signaling molecules within caveolae, cell–cell contacts, and focal adhesion plaques.

Mechanosensitive ion channels are present in endothelial cells and respond primarily to membrane tension, rendering them appropriate transducers for forces derived from osmotic or hydraulic gradients and shear stress. These channels are usually cation selective, passing Ca^{2+} as well as monovalent ions, but some are K^+ selective. The open probability

Figure 7 Proposed model for the activation of Akt/PKB and the phosphorylation of eNOS in response to the mechanical stimulation of an endothelial cell by fluid shear stress. The symbols on the left-hand side represent the cytoskeletal structure of the endothelial cell in the vicinity of a focal adhesion plaque, where many adaptor molecules and inactive protein kinases are localized (see text for explanation). Deformation of the endothelial cell by shear stress leads to a redistribution of stress across the endothelial structure, resulting in changes in the association of actin filaments and cytoskeleton-associated proteins. This leads to the activation of phosphatidylinositol 3-kinase (PI3K), which converts phosphatidylinositol bisphosphate (PIP₂) to phosphatidylinositol trisphosphate (PIP₃). The newly formed PIP₃ promotes the translocation of the inactive kinase Akt/PKB to the plasma membrane, where it is phosphorylated by phosphatidylinositol-dependent kinases (PDKs). The now activated Akt/PKB is able to dissociate from the PI3K and phosphorylate eNOS within the Akt/PKB recognition motif on Ser-1177 and stimulates NO production.

of these channels may be modulated by membrane potential and various ligands, although stress-activated ion channels may also be activated by virtue of cytoskeletal interconnections rather than directly through the plasma membrane. Other possible mechanisms by which endothelial cells may sense shear is through the glycocalyx, a layer of glycoproteins extending into the extracellular space, which may be displaced by shear stress to elicit an intracellular response.

THE IMMUNE SYSTEM CONSISTS OF A MULTIFACETED DEFENSE INVOLVING CIRCULATING LEUKOCYTES, BLOOD-BORNE FACTORS, AND CELL-BOUND MEDIATORS. ALTHOUGH THE IMMUNE SYSTEM PRIMARILY FUNCTIONS TO KILL PATHOGENS, INVASION OF MICROORGANISMS IS NOT A PREREQUISITE FOR IMMUNE ACTIVATION. ISCHEMIA–REPERFUSION, OR THE INTERRUPTION AND RESTORATION OF TISSUE BLOOD FLOW, IS A COMMON CLINICAL SITUATION (EXAMPLES INCLUDE ORGAN TRANSPLANTATION, BYPASS PROCEDURES, AND CEREBROVASCULAR DISEASES) THAT APPEARS TO RESULT IN IMMUNE SYSTEM ACTIVATION. THIS REGIONAL (E.G., STROKE) OR SYSTEMIC (E.G., HEMORRHAGIC SHOCK) VASCULAR DISORDER IS ASSOCIATED WITH AN OVERPRODUCTION OF OXYGEN FREE RADICALS AND PRODUCTION OF INFLAMMATORY MEDIATORS BY ACTIVATED ENDOTHELIAL CELLS, AS WELL AS THE ACTIVATION AND ENDOTHELIAL CELL ADHESION OF CIRCULATING BLOOD CELLS, SUCH AS LEUKOCYTES AND PLATELETS. THE INFILTRATION OF PLATELETS AND LEUKOCYTES INTO POSTISCHEMIC TISSUE IS ALSO FACILITATED BY AN INCREASED EXPRESSION OF ADHESION GLYCOPROTEINS AND MAJOR HISTOCOMPATIBILITY COMPLEX (MHC) MOLECULES ON THE SURFACE OF ENDOTHELIAL CELLS.

NITRIC OXIDE (NO), WHICH IS PRODUCED BY A VARIETY OF CELLS THAT PARTICIPATE IN THE IMMUNE RESPONSE, APPEARS TO CONTRIBUTE TO THE PATHOPHYSIOLOGICAL CHANGES ASSOCIATED WITH ISCHEMIA–REPERFUSION. NITRIC OXIDE EXHIBITS BOTH ANTI- AND PROINFLAMMATORY PROPERTIES THAT CAN INFLUENCE THE SEVERITY AND DURATION OF THE IMMUNE ACTIVATION ELICITED BY ISCHEMIA–REPERFUSION. THIS CHAPTER WILL ADDRESS THE IMMUNE SYSTEM ACTIVATION THAT OCCURS AFTER REPERFUSION OF ISCHEMIC TISSUES AND DISCUSS THE CONTROVERSIAL ROLE OF NO IN MODULATING THIS RESPONSE.

Ischemia–Reperfusion Enhances the Production of Cytotoxic Oxygen Radicals

Endothelium-Derived Oxygen Radicals

Tissue ischemia results in the depletion of intracellular adenosine triphosphate (ATP) stores, which subsequently compromises the function of membrane-associated, ATP-dependent ionic pumps in endothelial cells. This membrane

dysfunction allows entry of calcium, sodium, and water into the cells. The resultant accumulation of calcium and other ions in the cell can result in cell swelling and the inappropriate activation of cellular enzymes. One enzyme that is activated by the rise in intracellular calcium during ischemia is xanthine dehydrogenase (XDH). Under normal conditions, hypoxanthine (a breakdown product of ATP metabolism) is oxidized by XDH, in an NADH-dependent manner, to produce xanthine and uric acid. However, during the hypoxic

condition of ischemia, hypoxanthine levels rise within the cell due to ATP hydrolysis, and there is a calcium-dependent activation of proteases that convert the NADH-reducing XDH to an oxygen-reducing form of the enzyme, namely, xanthine oxidase (XO) (Granger, 1988). On restoration of blood flow (reperfusion) to the tissue and with the reintroduction of molecular oxygen, XO will convert hypoxanthine to xanthine and uric acid, and it will catalyze the reduction of molecular oxygen to form both superoxide anion radicals (O_2^-) and hydrogen peroxide (H_2O_2) (Fig. 1).

This XO-dependent mechanism of oxygen radical production has been invoked to explain the involvement of O_2^- and H_2O_2 in reperfusion injury to a variety of organs, including intestine, brain, heart, and skeletal muscle (Granger and Korthuis, 1995). The contention that XO contributes to the enhanced generation of oxygen radicals is largely based on studies demonstrating diminished oxygen radical-dependent tissue injury in animal models of reperfusion injury treated with XO inhibitors such as allopurinol or oxypurinol.

The tissue injury that is elicited by ischemia–reperfusion does not appear to be mediated by O_2^- or H_2O_2 per se, but by a product of the reaction of these two species which is more unstable and hence more reactive. The hydroxyl radical ($\cdot OH$) is formed by a spontaneous reaction between O_2^- and H_2O_2 that is catalyzed by metals such as iron (the iron-catalyzed Haber–Weiss or Fenton reaction) (Fig. 1). There is ample evidence that iron is mobilized from ferritin and other iron-sequestering proteins during ischemia and reperfusion. Hence, the metal is available for facilitation of $\cdot OH$ formation in postischemic tissues. A number of investigators have proposed that the highly cytotoxic $\cdot OH$ may directly account for the microvascular and parenchymal cell dysfunc-

tion that is manifested as reperfusion injury, whereas others attribute a more important role for XO-derived oxygen radicals (O_2^- and H_2O_2) as signaling molecules that subsequently recruit and activate neutrophils (Granger and Korthuis, 1995).

Neutrophil-Derived Oxygen Radicals

Neutrophils possess the membrane-associated enzyme NADPH oxidase, which allows leukocytes to generate large quantities of oxygen radicals (Granger and Korthuis, 1995). It is activated when neutrophils are exposed to inflammatory mediators, such as the leukotriene B_4 (LTB_4) and platelet activating factor (PAF) produced by endothelial cells. Neutrophilic NADPH oxidase reduces molecular oxygen to yield O_2^- , which in turn undergoes spontaneous dismutation to form H_2O_2 . Unlike H_2O_2 in endothelial cells, neutrophil-derived H_2O_2 does not participate in iron-catalyzed reactions to form $\cdot OH$, but rather participates in a reaction that yields hypochlorous acid ($HOCl$), which possesses 100 times the oxidizing and chlorinating potential of H_2O_2 . In the presence of myeloperoxidase (MPO), which is released from neutrophil granules on cellular activation, H_2O_2 reacts with chloride ions to form $HOCl$. Antioxidant enzymes are present in cells to decompose O_2^- and H_2O_2 , but similar detoxification mechanisms do not exist for $HOCl$.

Although both XO and neutrophilic NADPH oxidase contribute to the enhanced oxygen radical production observed in postischemic tissues, the two sources generate radicals at different times after the onset of reperfusion. Endothelial cell-associated XO appears to account for the enhanced oxidant flux that is observed within the first few

Figure 1 The xanthine oxidase pathway of oxygen radical production following ischemia–reperfusion. During ischemia, hypoxanthine levels build up as ATP is metabolized and xanthine dehydrogenase is converted to xanthine oxidase in a calcium-dependent manner. On reintroduction of oxygen to the tissue when it is reperfused, the xanthine oxidase converts the hypoxanthine to oxygen radicals (O_2^- and H_2O_2), xanthine, and uric acid.

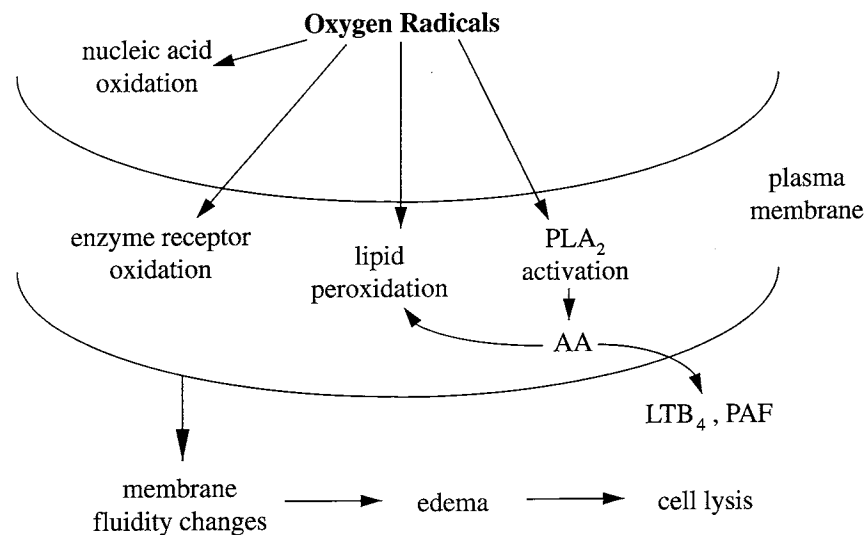

Figure 2 The mechanisms of oxidant-induced injury. The oxygen radicals attack the cell membrane, causing lipid peroxidation and release of inflammatory mediators such as LTB₄ and PAF. The net result of this is decreased cell membrane integrity, increased membrane permeability, and ultimately cell death.

minutes after reperfusion, while neutrophils account for the oxidant generation detected at 1–5 hours after reperfusion.

Mechanisms of Oxygen Radical-Mediated Tissue Injury

The plasma membrane is not only a site for the generation of oxygen radicals, but it is also a prime target for radical attack and damage (Fig. 2). Oxygen radicals can initiate injury by promoting lipid peroxidation of cell membranes and through oxidative modification of nucleic acids and enzyme receptors. Oxygen radicals can activate phospholipase A₂ (PLA₂) by increasing intracellular calcium. This activated enzyme releases lipid peroxyl free radicals, which promote further lipid peroxidation. Activation of PLA₂ also causes arachidonic acid (AA) to split off from membrane phospholipids. The AA is then metabolized by several enzymes to yield inflammatory mediators such as PAF and LTB₄. The lipid peroxidation initiated by oxygen radicals results in cell dysfunction, which is characterized by a loss of cell membrane integrity resulting from alterations in membrane fluidity and cell compartmentalization. Vascular endothelial cells may swell or lyse as a consequence of the aforementioned events. Consequences of these changes include a diminished endothelial barrier function, an increased vascular permeability, and interstitial edema.

Oxidants can also initiate leukocyte–endothelial cell adhesion. This action may result from oxidant-mediated generation of inflammatory mediators, which increase the expression of adhesion molecules on leukocytes, endothelial cells, or both. Alternatively, oxygen radicals may activate nuclear transcription factors [e.g., nuclear factor κ B (NF- κ B), activator protein-1 (AP-1)] that promote the biosynthesis of specific endothelial cell adhesion molecules (CAMs) such as

E-selectin and vascular cell adhesion molecule (VCAM-1). Both mechanisms (inflammatory mediator production and nuclear transcription factor activation) can result in the recruitment of inflammatory cells, which in turn can mediate the parenchymal cell and microvascular dysfunction observed in postischemic tissues. Neutrophil-derived HOCl and H₂O₂ can also disturb the balance of extracellular proteases and antiproteases, toward more proteolytic power. These oxidants can inactivate antiproteases (e.g., antitrypsin), thereby allowing neutrophilic proteases (e.g., elastase) to hydrolyze components of the vascular wall and interstitial matrix. This protease-promoting action is manifested at the interface between adherent leukocytes and vascular endothelial cells. A microenvironment exists between adherent leukocytes and the blood surface of vascular endothelial cells that is not subject to the “washout” effect of the flowing blood. As a result, the damage inflicted on endothelial cells by neutrophilic proteases and oxidants can be quite severe, as extracellular antiproteases and antioxidants are rapidly consumed in the protected microenvironment.

Antioxidants

The generation of oxygen radicals in postischemic tissues appears to overcome the capacity of endogenous antioxidants such as superoxide dismutase (SOD), catalase, glutathione, and NO to protect endothelial and parenchymal cells (Fig. 3). Exogenous antioxidants such as SOD and catalase have been shown to attenuate the leukocyte infiltration and tissue injury elicited by ischemia and reperfusion. Indeed, antioxidants have been successfully employed in preservation solutions for prevention of reperfusion injury to transplanted organs. Superoxide dismutase, which is normally found in the cytosol and mitochondria, catalytically dismu-

Antioxidants

Figure 3 Endogenous antioxidants, SOD, NO, and catalase are normally able to protect the endothelium from endogenous release of oxidants by participating in their conversion to less harmful metabolites. During ischemia–reperfusion, however, oxygen radical release overcomes the capacity of the antioxidants to prevent events such as leukocyte infiltration and tissue injury. Administration of exogenous sources of these antioxidants protects against ischemia–reperfusion-induced injury.

tates two molecules of $\text{O}_2^{\cdot -}$ to form oxygen and H_2O_2 . Nitric oxide can also react with $\text{O}_2^{\cdot -}$, but this reaction occurs at a rate that is three times faster than that catalyzed by SOD. The inactivation of $\text{O}_2^{\cdot -}$ by NO results in the formation of peroxynitrite, ONOO^- , a highly toxic oxidant. Catalase catalyzes the breakdown of H_2O_2 to water and oxygen rather than allowing it to be converted to the highly damaging $\cdot\text{OH}$.

Nitric Oxide Production Is Altered by Ischemia–Reperfusion

Biological Properties of Nitric Oxide

Nitric oxide is a highly reactive gas generated by endothelial cells, leukocytes, and platelets, among other cells. The NO produced by activated macrophages is used by these cells to kill phagocytosed bacteria. The huge intracellular production of NO results in oxidative damage to the invading microorganisms. Under normal physiological conditions, NO is continuously produced from oxidation of L-arginine by the enzyme nitric oxide synthase (NOS). The end products of this reaction are citrulline, nitrites, and nitrates (Fig. 4). Nitric oxide normally regulates its own release from endothelial cells through negative feedback on constitutive endothelial NOS (eNOS). Owing to its short half-life (3–5 s in a physiological salt solution), NO acts locally. It is both water and lipid soluble, and hence it readily permeates cells. Nitric oxide is important in maintaining vascular tone as a vasodilator. It has antiplatelet aggregation, antiplatelet activation, and antileukocyte adherence properties (Moncada and Higgs, 1993). Nitric oxide also appears to attenuate the accumulation of $\text{O}_2^{\cdot -}$, and it has been shown to prevent in-

creases in cellular membrane permeability (Fig. 4). However, there are also some cytotoxic actions of NO that are associated with the interaction of NO with $\text{O}_2^{\cdot -}$, resulting from the formation of ONOO^- . Any imbalance in the production of NO and $\text{O}_2^{\cdot -}$ can either lead to the formation of cytotoxic ONOO^- or result in an accumulation of protective NO, thereby explaining the controversy concerning the detrimental versus beneficial role of NO in experimental models of ischemia–reperfusion injury.

Nitric Oxide in Ischemia–Reperfusion

L-ARGININE

Plasma and tissue levels of NO have been reported to decline in some tissues exposed to ischemia–reperfusion (Fig. 5). This diminution of NO may result from endothelial injury or dysfunction. Although L-arginine supplementation has been shown to afford protection in some models of ischemia–reperfusion injury, the available evidence suggests that L-arginine availability should not be a rate-limiting factor in the generation of NO by endothelial cells *in vivo*. This contention has been challenged on the basis of observations in hypercholesterolemic animals, which appear to have an elevated plasma level of dimethyl-L-arginine, a naturally occurring inhibitor of NO synthase.

NITRATES AND NITRITES

Some investigators have reported an increase in plasma nitrate and nitrite levels during reperfusion of an ischemic tissue, suggesting that NO metabolism is increased in the post-ischemic period. However, others have observed a reduction in the plasma levels of these same metabolites. Nitrates and nitrites are also produced when NO interacts with $\text{O}_2^{\cdot -}$ to generate ONOO^- ; hence, the decline in nitrates/nitrites cannot be attributed to the enhanced $\text{O}_2^{\cdot -}$ production.

CONSTITUTIVE NITRIC OXIDE SYNTHASE ACTIVITY

The decrease in NO levels observed in some models of ischemia–reperfusion may reflect alterations at the level of NOS activity. It is only a matter of seconds from the engagement of cell membrane receptors by an appropriate stimulant before constitutive NOS (cNOS) activity is increased. Total cNOS activity has been shown to decrease following reperfusion, although this change is only detectable after 2 hours of reperfusion (Fig. 5). This explains why the NO synthesis inhibitor L-*N*^G-nitroarginine methyl ester only exacerbates ischemia–reperfusion injury if it is given early in the reperfusion period, but not at 4 hours of reperfusion when cNOS is already inhibited or depressed (Kanwar *et al.*, 1994). This may also explain why administration of L-arginine attenuates ischemia–reperfusion injury if given early, but not late, in the reperfusion period, as there is no cNOS to enzymatically convert it to NO.

INDUCIBLE NITRIC OXIDE SYNTHASE ACTIVITY

Inducible NOS (iNOS) requires *de novo* synthesis, and at least 4 hours of stimulation by cytokines or bacterial prod-

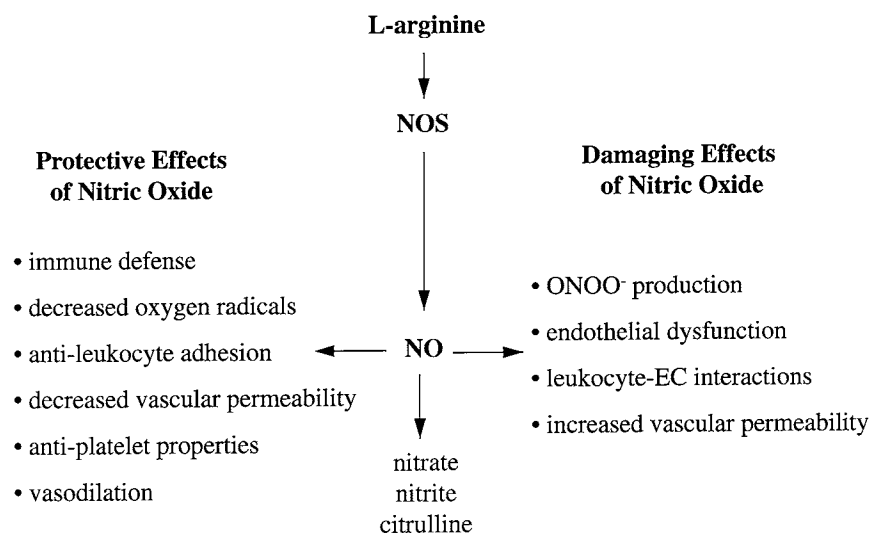

Figure 4 Nitric oxide can act as a protective or damaging agent following ischemia–reperfusion. It is generally accepted that too much NO release due to activation of iNOS following ischemia–reperfusion is the key to its deleterious effects, which include endothelial dysfunction and leukocyte–endothelial interactions. However, if a NO donor agent is administered early on in reperfusion it attenuates ischemia–reperfusion injury.

ucts such as endotoxin is normally required to detect iNOS activity in tissue. Once activated, iNOS can release NO from L-arginine at a constant rate for up to 36 hours. There is considerable controversy and uncertainty concerning the role of iNOS in ischemia–reperfusion injury. Some studies demonstrate that iNOS is undetectable after a few hours of reperfusion, despite the fact that several mediators of ischemia–reperfusion injury are known to induce iNOS activity (Kanwar *et al.*, 1994). Other studies show that it takes as little as 1 hour of reperfusion to demonstrate tissue activity of iNOS (Chandrasekar *et al.*, 1998), although studies

measuring both cNOS and iNOS demonstrate a decrease in cNOS activity before iNOS activity is seen.

It has been suggested that iNOS activation may contribute to the chronic responses to ischemia–reperfusion, such as those changes noted after organ transplantation. Indeed, excess NO production is one of the earliest signs of transplant rejection. Immunosuppressive drugs such as cyclosporine exert an inhibitory effect on iNOS, possibly by blocking the activation of the transcription factor NF- κ B. However, such an action would enable cyclosporine to interfere with the biosynthesis of a variety of inflammatory molecules (e.g.,

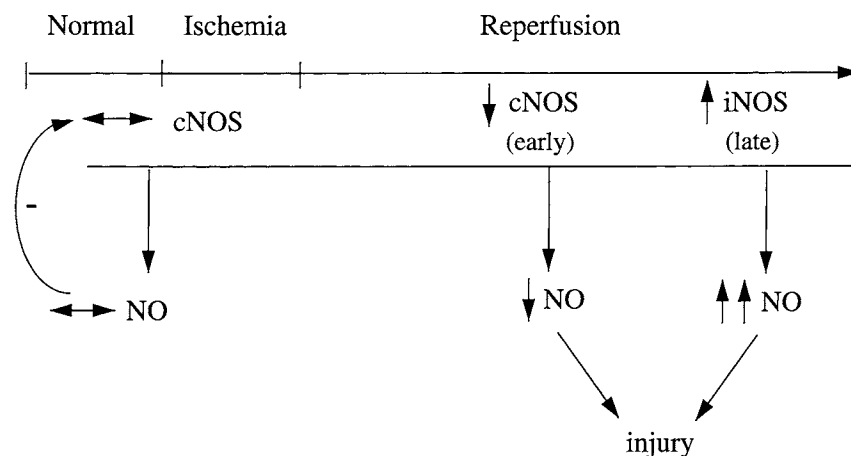

Figure 5 Nitric oxide synthase activity following ischemia–reperfusion. Constitutive NOS (cNOS) is continuously activated at basal levels. The resulting NO regulates its own production by negative feedback on cNOS. On the other hand, inducible NOS (iNOS) requires *de novo* synthesis and so takes longer to increase in activity. Early in reperfusion (a matter of hours) the levels of cNOS and NO fall. It is likely that iNOS levels increase after the drop in cNOS in the postischemic tissue, releasing large amounts of NO. Both of these changes in NOS activity may contribute to the ischemia–reperfusion injury.

cytokines, adhesion molecules) in addition to iNOS. Hence, the protection afforded by these compounds is not specific for iNOS.

Oxygen Radicals and Nitric Oxide Interact during Ischemia–Reperfusion

Damaging Effects

The interaction between NO and oxidants can result in either protective or damaging responses in postischemic tissue, depending on the source and production of NO and O_2^- . As discussed earlier, there is a burst of oxidant production and a decrease in NO levels immediately at the onset of reperfusion. Although endogenous SOD can inhibit O_2^- -induced inactivation of NO, reperfusion may also result in an inhibition of endogenous SOD and catalase activity. Consequently, the relative fluxes of O_2^- and NO generated by endothelial cells is likely to favor O_2^- accumulation during the early phase of reperfusion. This would limit the accumulation of NO and prevent any of its beneficial actions. Hence, NO-dependent vasodilation would be attenuated, and there would be a tendency for leukocytes to adhere to vascular endothelium and for platelets to aggregate. In the absence of NO, the O_2^- produced immediately after reperfusion will undergo spontaneous dismutation to form H_2O_2 . The H_2O_2 formed in this manner can promote the activation of PLA_2 and result in the generation of inflammatory mediators (e.g., PAF and LTB_4). In addition, peroxide can activate NF- κ B to promote the biosynthesis of endothelial CAMs. The net result of these changes is recruitment and activation of neutrophils into the postischemic tissues (Fig. 4).

Protective Effects

Nitric oxide can act in a tissue protective manner through vasodilation, attenuation of platelet aggregation, and leukocyte adherence (Fig. 4). It can also attenuate the accumulation of H_2O_2 in postischemic tissues by reacting with O_2^- , thereby interfering with the spontaneous or SOD-catalyzed dismutation of O_2^- . This O_2^- scavenging property of NO is supported by observations that inhibition of eNOS results in an oxidant stress in endothelial cells, and that NO-donating compounds can attenuate or abolish O_2^- -induced inflammatory responses such as leukocyte–endothelial cell adhesion.

Nitration of tyrosine residues produces nitrotyrosine, which is a sensitive marker of ONOO $^-$ activity. Nitrotyrosine levels are increased in postischemic tissues. Some studies have shown that blocking reperfusion-induced ONOO $^-$ production by inhibiting NOS activity worsens the injury response, presumably because the deleterious actions of decreased NO levels outweigh the diminished ONOO $^-$ levels. Ischemia per se does not increase the amount of nitrotyrosine in the tissue, as O_2^- is only released on reperfusion. The production of NO is what limits ONOO $^-$ generation in postischemic tissues. Although a 10-fold increase in both O_2^-

and NO should result in a 100-fold increase in ONOO $^-$ levels, such large increments in ONOO $^-$ generation are not likely to occur at the onset of reperfusion because of the early reduction in NO production that accompanies reperfusion. Although the protective effects of NO in reperfusion injury have often been attributed to its O_2^- -scavenging actions, evidence suggests that the product of this reaction (ONOO $^-$) may be protective in its own right, since it has been shown, in small quantities, to inhibit P-selectin-dependent leukocyte–endothelial adhesion and platelet aggregate formation (Lefer *et al.*, 1997).

Different Inflammatory Mediators Are Released during Ischemia–Reperfusion

Arachidonic Acid Metabolites

Reperfusion, probably as a consequence of enhanced oxidant production and increased intracellular calcium levels, causes the activation of PLA_2 . This in turn causes AA to be split off from membrane phospholipids. The AA is metabolized to produce eicosanoids via two pathways with different end products (Fig. 6). The first enzyme, lipoxygenase, produces leukotrienes from AA. Cyclooxygenase catalyzes the second pathway, producing prostaglandins (PGs) and thromboxane (Tx). Oxygen radicals are also involved in the subsequent conversion of certain eicosanoids such as TxA_2 and prostacyclin (PGI_2) to stable breakdown products called prostanooids, TxB_2 and 6-keto- $PGF_{1\alpha}$, respectively. Most of these factors can be released from endothelial cells and neutrophils.

LEUKOTRIENES

Leukotrienes act as chemoattractants and chemoactivators. Leukotriene B_4 is a widely documented chemoattractant for neutrophils, attracting them to the vascular endothelium where they can come in contact with many AA metabolites and other stimulants. It may also directly activate the neutrophils to produce other chemoactivators such as TxA_2 , PGE_2 , PAF, and oxygen radicals, as well as cytotoxic proteases such as elastase and collagenases (Karasawa *et al.*, 1991). An outcome of the accumulation of these inflammatory substances is adhesion of neutrophils, damage to the endothelium, increased permeability, and subsequent transmigration of the neutrophils into the tissue where they can cause further damage. Nitric oxide does not prevent LTB_4 -induced neutrophil adhesion to the endothelium of postcapillary venules, and so its protective role in reperfusion injury is not likely to involve direct interference with LTB_4 responses. The inability of NO to interfere with LTB_4 -mediated inflammatory responses likely reflects the fact that LTB_4 is a weak stimulant of neutrophilic O_2^- formation.

THROMBOXANE

Thromboxane A_2 is a vasoconstrictor that opposes any vasodilatory actions of NO. It is released from neutrophils,

Figure 6 The arachidonic acid cascade. On exposure to oxygen radicals, PLA₂ is activated and splits AA from membrane phospholipids. The AA is metabolized by two different enzymes. Lipoxygenase produces leukotrienes from AA. Cyclooxygenase produces prostaglandins (PGs) and thromboxane (Tx) from the AA. Many of these products lead to leukocyte–endothelial interactions and microvascular permeability. Prostacyclin (PGI₂) has been shown to protect against these injuries.

platelets, and endothelial cells. It can cause injury by increasing vascular permeability both via a direct action on endothelial barrier function and by promoting the transmigration of neutrophils through the vascular wall.

PROSTAGLANDINS

Most prostaglandins are proinflammatory and cause vasoconstriction. However, PGI₂, or prostacyclin, is anti-inflammatory and vasodilatory. Hence, this cyclooxygenase product shares many of the properties of NO. Following reperfusion, more vasoconstricting than vasodilating substances may be released, which may lead to further ischemia. Thus, the relative levels of PGI₂, NO, and TxA₂ in postischemic tissues are important determinants of the extent and duration of reperfusion after an ischemic insult.

Other Mediators

PLATELET ACTIVATING FACTOR

Platelet activating factor is also formed from a membrane phospholipid by the action of PLA₂ (Hourani and Cusack, 1991). Newly synthesized PAF is placed on the blood front of vascular endothelial cells, where it is accessible to neutrophils that are rolling along the cell surface (Fig. 7). Platelet activating factor is a potent chemoattractant and activator of neutrophils, which respond with a large flux of O₂^{•−}. Unlike for LTB₄, NO-donating compounds attenuate the oxidant-dependent PAF-induced adhesion of neutrophils to endothelium. Superoxide dismutase exerts the same action on PAF-induced inflammation; therefore, the beneficial effects of NO may relate to its ability to scavenge O₂^{•−}.

MAST CELL PRODUCTS

Ischemia–reperfusion elicits an increased microvascular permeability that exhibits both leukocyte adhesion-dependent and -independent components. Nitric oxide has been shown to blunt both the adhesion-dependent and -independent components of this vascular permeability response. The early, leukocyte-independent microvascular leak observed in postischemic tissues may result from the activation of mast cells, which release oxygen radicals and inflammatory mediators such as histamine (Fig. 7). Nitric oxide appears to regulate the stability of mast cell membranes. Hence, the decrease in NO levels that occurs early after reperfusion may contribute to the concomitant mast cell degranulation that is observed along the length of postcapillary venules. The fact that mast cell-stabilizing agents afford some protection against the early microvascular leak in much the same manner as NO-donating agents lends support to the concept that mast cell products contribute to reperfusion injury.

PROTEOLYTIC ENZYMES

Activated neutrophils produce proteolytic enzymes, including elastase, collagenase, and cathepsin G (Fig. 7). With neutrophils, these proteases can be released into the microenvironment between adherent neutrophils and the endothelium. This allows for an accumulation of proteases on the endothelial cell surface, where different glycoproteins (e.g., glycocalyx, adhesion molecules) are hydrolyzed. The proteases also attack the intercellular endothelial and interstitial matrix proteins. Elastase, for example, digests elastin, fibronectin, fibrinogen, and collagen. This causes destruction of the basement membrane to which endothelial cells are attached. Oxygen radicals promote the release of neutrophilic

Figure 7 Oxygen radicals stimulate the release of PAF from a membrane phospholipid and also stimulate AA activation. In addition, neutrophils are stimulated to produce proteases that attack proteins, including those of the basement membrane matrix. Monocytes, lymphocytes, and endothelial cells release cytokines in response to oxidants. The oxygen radicals released following ischemia–reperfusion also cause mast cell degranulation, resulting in the release of yet more inflammatory mediators.

proteases and inactivate protease inhibitors such as α_1 -protease, which inhibits elastase (Korthuis *et al.*, 1994). Nitric oxide can both inhibit and stimulate the release of proteases. Its protective effects may be mediated through an intracellular cGMP-dependent signal transduction pathway.

CYTOKINES

Lymphocytes, macrophages, endothelial cells, and other cells produce and secrete cytokines such as tumor necrosis factor alpha (TNF- α), γ -interferon (IFN- γ), and interleukin 1 (IL-1). These cytokines can contribute to the pathobiology of ischemia–reperfusion injury by engaging with their specific receptors on endothelial cells and macrophages to promote the increased biosynthesis of proteins such as endothelial CAMs and iNOS. Both the production and actions of cytokines are linked to activation of NF- κ B. Oxygen radicals, which are potent stimuli for the production and release of cytokines, promote cytokine generation in postischemic tissues by activating NF- κ B. This transcription factor normally resides in the cytosol bound to an inhibitory factor, I κ B. The degradation of I κ B allows NF- κ B to translocate into the nucleus, where it binds to response elements on cytokine genes to promote their synthesis.

The iNOS gene has two binding sites for NF- κ B. Although cytokines could potentially participate in a positive feedback loop involving oxygen radicals, NF- κ B, and iNOS, there is evidence to suggest otherwise, at least within the first hours of reperfusion. However, days after an ischemic insult, cytokines and iNOS have been noted to increase in parallel with the increased expression of endothelial CAMs. These observations suggest that cytokines enhance, in an NF- κ B-dependent fashion, the biosynthesis of iNOS, which in turn pro-

duces large quantities of NO in the late postischemic period (Chandrasekar *et al.*, 1998). Conversely, there is some evidence that NO can inhibit IL-1 and TNF- α release from macrophages. In addition, NO attenuates reoxygenation-induced upregulation of the CAM intercellular adhesion molecule-1 (ICAM-1), probably by decreasing the oxidative stress-induced NF- κ B activation that can lead to increased ICAM-1 expression (Kupatt *et al.*, 1997). These studies support the contention that NO may exert both pro- and anti-inflammatory effects in tissues exposed to ischemia and reperfusion.

Nitric Oxide Modulates Leukocyte–Endothelial Interactions Induced by Ischemia–Reperfusion

Leukocyte Infiltration in Postischemic Tissue

One of the key events in the pathogenesis of reperfusion injury is the interaction between activated leukocytes and microvascular endothelium. Because of their abundance and chemotactic attraction to complement 5a, which is mobilized quickly to sites of damage, neutrophils are usually the dominant cell type observed in the initial phases of an inflammatory response. Neutrophils may mediate both morphological and functional lesions during reperfusion, as neutrophil depletion blocks the increased capillary leak caused by ischemia–reperfusion. Leukocytes must adhere to vascular endothelium in order to accumulate in tissues and cause damage. To facilitate this accumulation of leukocytes, the expression of adhesion glycoproteins is increased on the surface of activated leukocytes and endothelial cells. The endothelial CAMs act as receptors for ligands expressed on

leukocytes or platelets, and they allow leukocytes not only to adhere but also to emigrate through the endothelial barrier into the interstitium, where they can injure parenchymal cells (Panes and Granger, 1998).

Not all adherent leukocytes transmigrate into the tissue. Some detach and reenter the circulation. Since activated leukocytes are stiffer than their unactivated counterparts, trapping within the pulmonary vasculature or in other distant capillary beds is often a result of ischemia–reperfusion. Platelets also aggregate to each other and to leukocytes in the microvasculature of postischemic tissues, where they release various mediators of inflammation and increase vascular permeability. A second wave of leukocyte infiltration follows, with monocytes/macrophages and lymphocytes playing a role in the maintenance of the ischemia–reperfusion-induced injury. This pattern of cellular infiltration is associated not only with the expression of adhesion molecules but also with MHC upregulation (Takada *et al.*, 1997).

Forces Acting on the Leukocytes

Shear force, provided by the flowing blood parallel to the endothelial cell surface, normally limits the contact area between endothelial cells and leukocytes. After reperfusion of ischemic tissues, shear rate is reduced in both arterioles and venules. Since endothelial NO production is directly related to shear rate, the low blood flow associated with reperfusion may explain the accompanying decline in NO production.

Studies of leukocyte adhesion over a wide range of venular shear rates have demonstrated an inverse relationship between the number of adherent leukocytes and shear rate; that is, leukocyte adhesion rises as shear rate is reduced, whereas it decreases when shear rate is elevated. This observation suggests that the lower shear rate that occurs in the microcirculation after reperfusion serves to facilitate the recruitment of adherent leukocytes. Although the tendency for leukocytes to adhere to endothelium at low shear rates is often attributed to the ability of leukocytes to establish stronger adhesive contacts with the endothelial cell surface, it is also possible that a diminished production of NO at low shear rates could promote the adhesion of leukocytes.

Mechanical Disturbances

Apart from the release of harmful substances, neutrophils are thought to contribute to reperfusion injury by mechanical means, that is, by plugging capillaries. The increased stiffness of activated neutrophils, coupled with endothelial swelling, may account for the propensity for neutrophil trapping in capillaries after reperfusion (“capillary no-reflow”). The tendency for platelets to form aggregates with other platelets and to form platelet–leukocyte aggregates after reperfusion of ischemic tissues may also explain the capillary obstruction and malperfusion that is observed on reperfusion. Reperfusion-induced capillary no-reflow can be attenuated by administration of SOD or NO donor agents, suggesting that alterations in the balance between NO and O_2^- pro-

duction may be a critical determinant of leukocyte capillary plugging.

Leukocyte–Endothelial Interactions

As noted in Fig. 8, the interaction between leukocytes and vascular endothelium can be divided into three steps, each governed by different families of CAMs. Initially, the leukocytes become “sticky” and roll along the endothelial cell surface at a velocity that is lower than the movement of red blood cells. This tentative initial interaction is mediated by members of the selectin adhesion molecule family, which are found on the surface of both the leukocytes and endothelial cells. Their corresponding ligands on the other cell include sialylated Lewis X and A blood group antigens. Adherence of leukocytes to the vessel wall follows, where the firm attachment is primarily mediated by integrins on the leukocytes and members of the immunoglobulin superfamily on the endothelial cell. These CAMs are also involved in the subsequent transmigration of leukocytes through the vascular endothelial barrier, although the nature of the bonds is likely to be different from those that mediate adherence. The levels of expression of CAMs on both the leukocyte and endothelial cell are increased under inflammatory conditions such as ischemia–reperfusion (Panes and Granger, 1998).

Adhesion Molecules

ROLLING LEUKOCYTES

Adhesion of neutrophils to cultured endothelial cells is rapidly initiated by agents that increase cytosolic calcium. Thrombin, H_2O_2 , and LTB_4 are examples of agents that cause a rapid (1–2 min) fusion of Weibel–Palade bodies (storage granules for P-selectin and von Willebrand factor) with the endothelial cell membrane, leading the subsequent release of von Willebrand factor and the translocation of P-selectin [or granule membrane protein-140 (GMP-140)] to the surface of the endothelial cells. This adhesion molecule is a member of the selectin family that mediates leukocyte rolling, which is a prerequisite for (and precedes) firm attachment of leukocytes to the vessel wall. Once mobilized, P-selectin probably acts as a ligand to glycoproteins such as P-selectin glycoprotein ligand (PSGL) or sialylated Lewis X on the surface of neutrophils and monocytes. In the absence of these inflammatory cells, P-selectin rapidly disappears (within 5 to 10 min) poststimulation. P-selectin can also be upregulated after cytokine stimulation, via a transcription-dependent pathway, requiring about 4 hours for peak expression.

Another member of the selectin family, L-selectin, is constitutively expressed on neutrophils, monocytes, lymphocytes, and other myeloid cells. It is involved in initial tethering of leukocytes. It binds to P-selectin and E-selectin among others and is rapidly shed from the leukocyte surface on activation.

The neutrophil-specific ligand endothelial–leukocyte adhesion molecule-1 (ELAM-1 or E-selectin) is not present in normal tissue, but its expression is increased on cytokine-

Figure 8 The three stages of leukocyte-endothelial interactions following ischemia-reperfusion. (1) Rolling is supported by the selectin group of CAMs and sialylated Lewis A and X blood group antigens. (2) In adherence, the leukocytes adhere firmly to endothelial cells. This interaction is mediated by integrins on the leukocyte surface and immunoglobulins on the endothelial cells. (3) In transmigration, the adhesion bonds change as the leukocytes emigrate between or through endothelial cells into the interstitium beyond. Neutrophils are the first cells to interact with the vessel wall following ischemia-reperfusion. Hours or days later monocytes and lymphocytes also adhere and emigrate as the injury progresses.

activated venular and capillary endothelial cells. It is induced in a transcription (NF- κ B)-dependent manner. Following reperfusion, peak expression of E-selectin coincides with peak neutrophil infiltration into the tissue, and it precedes the transmigration of monocytes and lymphocytes.

ADHESION AND EMIGRATION OF NEUTROPHILS

Complement 5a, PAF, LTB₄, and a variety of other inflammatory mediators are known to increase the expression and/or avidity of adhesion glycoproteins (β_2 -integrins) on leukocytes that facilitate firm adhesion to endothelial cells. The β_2 -integrins share a common β (CD18) subunit that is non-covalently linked to an α subunit (CD11a, CD11b, CD11c). These heterodimers can bind to ICAM-1 and ICAM-2 on endothelial cells. The ubiquitously distributed immunoglobulin ICAM-1 is basally expressed at low levels on endothelial cells, whereas ICAM-2 is constitutively expressed in moderate quantities. The expression of ICAM-1 on endothelial cells is transcription-dependent, with cytokines and oxygen radicals serving as potent stimuli for upregulation. Expression is significantly increased after ischemia-reperfusion, reaching a stable level by 24 hours postischemia. In different models of ischemia-reperfusion, ICAM-1 knockout mice exhibit a blunted leukocyte recruitment response and protection against microvascular and parenchymal cell injury. Similar protection is observed in CD11/CD18-deficient mice and in mice receiving monoclonal antibodies directed against either ICAM-1 or CD11/CD18. Hence, the interaction between CD11/CD18 on leukocytes and ICAM-1 on endothelial cells is considered to be the major determinant of

reperfusion-induced leukocyte recruitment and the consequent tissue injury.

Another endothelial CAM, platelet-endothelial cell adhesion molecule (PECAM-1), may also be involved in the adhesion and transmigration of neutrophils in postcapillary venules. It is expressed on neutrophils, platelets, and endothelial cells, and it is homophilic in its interaction, that is, binds only to other PECAM-1 molecules. Unlike other CAMs, the expression of PECAM-1 is unaltered by cytokines, oxygen radicals, or ischemia-reperfusion.

Initial rapid recruitment of neutrophils from the circulation is mediated by P-selectin and L-selectin, PAF, and the β_2 -integrins. The more sustained wave of leukocyte recruitment is mediated by E-selectin, IL-8, and β_2 -integrin-ICAM-1 interactions. It has been proposed that neutrophils binding through E-selectin to cytokine-activated endothelial cells encounter IL-8, activate the β_2 -integrins, and undergo transmigration. At later times, E-selectin declines, but ICAM-1 and VCAM-1 continue to rise. This sequence of events creates an endothelial cell surface that favors neutrophil adhesion initially then becomes more adhesive for monocytes and lymphocytes.

Role of Other Leukocyte Populations in Ischemia-Reperfusion Injury

Lymphocytes, including T cells and lymphokine-activated killer cells, can injure the endothelial cells via oxygen-independent mechanisms. The adhesion molecule CD11a/CD18 (also known as lymphocyte function-associated anti-

gen, LFA-1) can undergo molecular activation in T lymphocytes, markedly increasing the avidity for its ligands, ICAM-1 and ICAM-2. T-cell-dependent cytotoxicity may be influenced by ICAM-1 and can be completely inhibited by an anti-ICAM-1 monoclonal antibody. Another immunoglobulin adhesion molecule, VCAM-1, is normally found on epithelial cells but not on vascular endothelium. However, VCAM-1 is synthesized and expressed on endothelial cells following transcription in response to IL-1 or TNF- α treatment. Both ICAM-1 and VCAM-1 appear to show some complementary distribution: ICAM-1 is constitutively expressed on capillaries and can be induced on epithelium, whereas the opposite holds for VCAM-1 expression. The VCAM-1 ligand on the leukocyte is the β_1 -integrin very late antigen (VLA-4), which is expressed by lymphocytes and monocytes, and probably neutrophils. The T lymphocytes that migrate into inflammatory sites may be memory T cells, that is, those that have been previously stimulated by antigen. These memory T cells are more adherent than naive T cells to cytokine-activated endothelial cells *in vitro*, and they uniquely appear to induce increased endothelial permeability by a contact-dependent pathway. Compared to naive cells, memory T cells have diminished expression of L-selectin but increased expression of CD44. Both VLA-4 and CD44 can mediate the binding of T cells to inflamed venules.

Transmigration of lymphocytes appears to involve the interaction of LFA-1 and ICAM-1 *in vitro*. Nevertheless, the endothelial ICAM-1–lymphocyte LFA-1 pathway is probably not of critical importance, as humans lacking the LFA-1 receptor still have lymphocytes that infiltrate inflammatory sites, whereas their neutrophils cannot. The β_1 -integrins such as VLA-4 and extracellular matrix components, for example, laminin, collagen, and fibronectin, are probably involved in lymphocyte transmigration. P- and E-selectin may also be involved directly or indirectly in lymphocyte emigration, as blocking these receptors inhibits tissue infiltration by lymphocytes.

Role of Nitric Oxide in Leukocyte–Endothelial Interactions

NEUTROPHILS

Inhibition of NOS activity with L-arginine analogs elicits microvascular and inflammatory responses that are very similar to those observed after ischemia–reperfusion, including neutrophil adherence to venular endothelium and emigration into the interstitium. Nitric oxide synthase inhibition also has been shown to elicit an oxidant stress in venular endothelium, presumably due to the absence of the highly efficient O_2^- scavenger, NO. Mast cell degranulation and platelet–leukocyte aggregation are additional features that are shared by ischemia–reperfusion and NOS inhibition. In some models of reperfusion injury, NOS inhibition exacerbates certain aspects of the injury response, including neutrophil adhesion and vascular permeability. Additional support for a role for NO in reperfusion injury comes from reports that NO-donating compounds attenuate the leukocyte–endothelial

cell adhesion, platelet–leukocyte aggregation, mast cell degranulation, and increased vascular permeability that are normally elicited by ischemia–reperfusion (Kurose *et al.*, 1994). These actions may also reflect the O_2^- -scavenging properties of NO, as SOD administration is also effective in blunting the same responses to ischemia–reperfusion.

The observation that NO is protective only in those reperfusion injury models that require the presence of neutrophils suggests that NO exerts its beneficial actions on the leukocyte, endothelial cell, or both. Since it has been shown that NO can inhibit the expression of P-selectin (Gauthier *et al.*, 1994), ICAM-1, and VCAM-1 on endothelial cells and E-selectin, ICAM-1, and VCAM-1 in plasma (Engelman *et al.*, 1995) *in vivo*, it appears likely that endothelial cells are a target of NO action in models of ischemia–reperfusion. It has been difficult to demonstrate such an inhibitory effect of NO donors on CAM expression in cultured endothelial cells, suggesting that the inhibitory actions observed *in vivo* may reflect an effect of NO on cytokine and/or oxygen radical production/accumulation. Spieker *et al.* (1998) showed that NO can block the TNF- α -induced upregulation of E-selectin, ICAM-1, and VCAM-1, probably by promoting the activity of the I κ B- α promoter and thereby preventing NF- κ B translocation into the nucleus and subsequent CAM gene transcription.

OTHER LEUKOCYTE POPULATIONS

There is growing evidence that lymphocytes may contribute to the pathogenesis of ischemia–reperfusion injury. Studies performed in severe combined immunodeficient (SCID) mice, which have no lymphocytes, have revealed an attenuated response to ischemia–reperfusion. Reconstitution of the T cell, but not B cell, population in SCID mice restores the normal pathological alterations to ischemia–reperfusion. Furthermore, it has been shown that depletion of CD4 $^+$, but not CD8 $^+$, T cells blunts the tissue injury associated with ischemia–reperfusion. These observations suggest that CD4 $^+$ T cells contribute to the microvascular and parenchymal cell dysfunction associated with ischemia and reperfusion. The mechanisms involved in CD4 $^+$ T-cell-mediated, reperfusion-induced tissue injury are poorly defined. However, some evidence suggests that the T cells may act to modulate the recruitment of neutrophils by modulating the expression of certain endothelial CAMs. Although NO plays an important role in regulating neutrophil recruitment and function, it appears to exert little influence on lymphocytes (Cartwright *et al.*, 1997), possibly because lymphocytes do not produce oxygen radicals.

Ischemia–Reperfusion Promotes Leukocyte–Platelet Interactions

Platelet Interactions

Ischemia–reperfusion is known to activate and promote the aggregation of platelets. In addition, reperfusion is often

associated with the formation of platelet–leukocyte aggregates. These aggregates form on the surface of endothelial cells lining postcapillary venules of the postischemic tissue, where they are dislodged by flowing blood to enter the circulation. The dislodged aggregates are then trapped within capillaries of the liver, lung, or other organs. The plugging of capillaries by these aggregates can lead to a reduction in blood flow and cellular necrosis. In addition, the aggregates can produce and release a variety of mediators that can elicit an increased vascular permeability. P-selectin, which is synthesized, stored in α -granules, and expressed on the surface of activated platelets, mediates the heterotypic aggregation of leukocytes and platelets. P-selectin-deficient mice and mice receiving monoclonal antibodies directed against P-selectin produce fewer leukocyte–platelet aggregates within postcapillary venules exposed to ischemia–reperfusion.

The Influence of Nitric Oxide on Platelet Function

Activated platelets release adenosine diphosphate and serotonin. These substances can bind to endothelial cell receptors to stimulate the formation and release of NO, which modulates platelet function (Cheung *et al.*, 1997). Nitric oxide can act synergistically with PGI₂, metabolites of ectonucleotidase, and lipoxygenase to influence platelet function. Nitric oxide prevents platelet aggregation and promotes disaggregation of preformed aggregates. In addition, NO attenuates platelet adhesion to leukocytes and to endothelium. These actions of NO may be partially mediated by the activation of soluble guanylate cyclase. Nitric oxide is known to inhibit P-selectin expression on platelets and endothelial cells. This may account for the inhibitory action of NO on the binding of platelets to endothelial cells and leukocytes, but not the homotypic aggregation of platelets.

Major Histocompatibility Complexes in Ischemia–Reperfusion Injury: Does Nitric Oxide Play a Role?

What Are Major Histocompatibility Complexes?

Nearly all vertebrate species studied have been shown to possess highly polymorphic cell surface molecules. These antigenic molecules are coded for by the human leukocyte antigen (HLA) genes as alleles of HLA-A, -B, and -C (class I) and HLA-DR, -DQ, and -DP (class II) loci. The HLA genes are also known as the MHCs, and the plasma membrane proteins they encode are often referred to as MHC I and MHC II. Class I antigens are found on virtually every cell in the body except for erythrocytes. Class II antigens are found only on the surfaces of macrophages and a few other cell types, including B cells. Identical MHC genes are not shared except between identical twins. The main role of these molecules is to govern immune recognition by presenting self and nonself antigenic peptides to the immune system. Only when an antigen is bound to an MHC protein

on an antigen presenting cell (e.g., a macrophage to form an MHC–peptide complex) can a T cell recognize and bind to it. This binding is necessary to trigger a transduction cascade leading to T-cell activation, differentiation, and initiation of the antigen-specific immune response. The different subsets of T cells require the peptide to be complexed to different MHC molecules. Cytotoxic and suppressor T cells bind to MHC I-associated antigens and are CD8-positive, and helper T cells bind to MHC II-associated antigens and are CD4⁺. The CD4 and CD8 molecules exist in a complex with the T-cell receptor (TCR) and CD3 (T cell phenotype) (Fig. 9). Also on the T cells are other accessory molecules, LFA-1 and CD2. The VLA-4 molecule mediates lymphocyte recirculation patterns and increases binding of the T cell to MHC antigens, contributing to antigen-dependent immunity.

The MHC I molecules have a high affinity to endogenous, synthesized antigens such as viral antigens, whereas MHC II types primarily present peptides derived via endocytosis. Cross-linking of the TCR–CD3 complex by binding the MHC molecule transiently converts the β_2 -integrin (LFA-1) from low avidity to high avidity. This provides a mechanism for regulating cellular adhesion and deadhesion in an antigen-specific manner. It also allows lymphocytes to adhere more strongly to vascular endothelium and transmigrate. Anti-LFA-1 monoclonal antibodies decrease the T cell response by inhibiting T-cell-directed cytolysis and adhesion of target cells (Heemann *et al.*, 1994). The presence of either CD4 or CD8 molecules in the TCR complex produces a considerably stronger impulse for T-cell activation on binding the MHC proteins than binding of the TCR–CD3 complex alone. The signal transduction that occurs after the TCR binds to the antigen is regulated by the CD3 part of the TCR–CD3 complex, not by the TCR molecule. The CD2 molecule binds to LFA-3 on the antigen-presenting cells.

Figure 9 Major histocompatibility complexes are upregulated following ischemia–reperfusion. Normally they present antigens to T cells. The MHC–antigen complex binds a complex of CD4/CD8, TCR, and CD3 on the lymphocytes. Enhancing this interaction, the accessory molecules VCAM-1, LFA-3, and ICAM-1/2 bind their respective ligands on the lymphocytes. The LFA-1 molecule is converted from low to high avidity when the MHC receptor is cross-linked with the TCR complex, allowing the lymphocytes to adhere to vascular endothelium and transmigrate.

Major Histocompatibility Complexes in Ischemia–Reperfusion

The upregulation of ICAM-1 and recruitment of neutrophils that is elicited by ischemia–reperfusion precedes the increased expression of MHC molecules (Takada *et al.*, 1997). This MHC upregulation is associated with lymphocyte and macrophage infiltration. Since it follows the expression of lymphocyte products such as IL-2, IFN- γ , and TNF- α , some of these products may be responsible for the increase in MHC expression. Blocking both P- and E-selectin blocks the infiltration of all leukocytes into the postischemic tissue and prevents both MHC II induction and the expression of the inflammatory products of the leukocytes. Although these findings demonstrate profound changes in MHC II induction after ischemia–reperfusion, the significance of these changes to the pathobiology of reperfusion injury remain poorly defined.

Regulation of Major Histocompatibility Complex Expression: Role of Nitric Oxide

Nitric oxide has a controversial role in the regulation of MHC expression. It has been shown to downregulate MHC expression in several models of immune activation such as IFN- γ -induced MHC expression. However, IFN- γ can also cause NO production, and TNF- α can further increase IFN- γ -induced MHC II and NO upregulation, although these are through different signaling pathways (Hellendall and Ting, 1997). The NO produced in response to IFN- γ seems to be protective against other pathways in inflammation. Conversely, NO may cause MHC II upregulation in certain cells, although this is important for the development of immunocompetent activity of the cells. Other studies show no influence of NO on MHC expression induced by IFN- γ , TNF- α , or IL-1. What about the other way around? In macrophages, cross-linkage of MHC I or II actually triggers NO release. Macrophages can produce NO by two different pathways that involve T-cell-derived cytokines. The MHC II molecule may act as a transmembrane signal transducer that ultimately causes NO production when the T cell engages the macrophage MHC II receptor. Hence, these findings indicate that the role of NO in reperfusion-induced MHC upregulation remains poorly understood.

Nitric Oxide Modulates Reperfusion-Induced Tissue Injury

Vascular Permeability

A well-characterized response of the microvasculature to ischemia–reperfusion is endothelial barrier dysfunction leading to increased vascular permeability. Leukocytes appear to be key mediators of the increased permeability associated with ischemia–reperfusion. Several lines of evidence sup-

port this view: (1) the magnitude of the increased albumin leakage across venules exposed to ischemia–reperfusion is significantly and positively correlated with the number of adherent and emigrated leukocytes in these vessels, (2) monoclonal antibodies directed against leukocyte or endothelial CAMs attenuate reperfusion-induced increases in vascular permeability, and (3) a variety of agents (e.g., SOD, adenosine, allopurinol) that blunt the leukocyte recruitment response to ischemia–reperfusion also diminish the vascular permeability response. Nitric oxide-donating compounds have also proved to be very effective in reducing reperfusion-induced increases in leukocyte adhesion and the concomitant increase in vascular permeability in certain vascular beds. Since NO donors are so effective in reducing leukocyte adhesion, it is generally assumed that the attenuated permeability is directly related to the blunted leukocyte traffic across the vascular wall. However, the molecular basis for the protection afforded by NO in this leukocyte-dependent increase in vascular permeability remains unclear. This is made evident by reports demonstrating that in leukocyte-independent models of acute inflammation, nitric oxide per se appears to promote endothelial barrier dysfunction. A potential explanation for this discrepancy is that the elevated O_2^- fluxes in leukocyte-dependent models may favor a protective role effect of NO, whereas the low O_2^- fluxes generally associated with non-leukocyte-dependent models may minimize the contribution of NO.

Cell Death

There are two types of cell death following ischemia–reperfusion (Fig. 10). Necrosis is characterized by cell swelling and membrane rupture, allowing the contents of the cells to leak into the surrounding environment. The contents include damaging oxygen radicals, proteases, and other inflammatory mediators that can cause damage to the surrounding tissue, possibly leading to the death of the tissue or organ. The other process leading to cell death is apoptosis (Duke *et al.*, 1996). This is known as non-necrotic cell suicide and is a form of programmed cell death. This process is associated with cell shrinkage, membrane blebbing, chromatin condensation, and DNA fragmentation. The cells split into plasma membrane-bound vesicles known as apoptotic bodies. These are phagocytosed by neighboring cells and tissue macrophages, and so nearby cells are not exposed to harmful cellular contents.

APOPTOSIS

Following brief ischemic episodes, apoptosis usually prevails as the dominant cause of cell death in injured cells. However as the length or severity of ischemia increases, the scales tip toward necrotic death. Apoptosis can be seen within half a day following just a few minutes of ischemia. However, necrosis requires longer than that to be detected in most tissues, and it can be seen within a day of the injury. The oxidative stress that is elicited by ischemia–reperfusion

Figure 10 Cell death following ischemia–reperfusion. Cells that die by apoptosis break up into membrane-bound vesicles that are phagocytosed by neighboring cells and tissue macrophages. When cells die by necrosis, however, they swell and lyse, releasing their harmful contents into the surrounding milieu, which can damage other cells or cause them to die.

is known to induce apoptosis. Nitric oxide appears to be both beneficial and detrimental to the process of apoptosis; that is, it is protective if released from cNOS and harmful if released from iNOS. The increase in iNOS activity that is observed after reperfusion may be caused by $\text{TNF-}\alpha$, which also induces apoptosis (Ferrari *et al.*, 1998). Many treatments that block iNOS activity also block apoptosis. On the other hand, L-arginine has been shown to prevent the apoptosis elicited by reperfusion; however, it remains unclear whether this action is directly related to NO production (Calabrese *et al.*, 1997).

NECROSIS

After a prolonged ischemic period, less than an hour in many cases, cells die due to necrosis. Nitric oxide can prevent this cellular necrosis if administered early in the reperfusion period. However, if administered at a time when iNOS is significantly upregulated, then the exogenous NO could prove toxic and exacerbate the tissue injury.

Organ Dysfunction

Ischemia–reperfusion-induced oxygen radical generation may result in endothelial cell injury and leukocyte activation. These cells release other harmful mediators that attract other leukocytes and that promote the release of other inflammatory substances. The leukocytes infiltrate the tissue, where they can inflict injury to parenchymal cells. In the heart, for example, reperfusion is associated with myocyte

injury and cardiac dysfunction (Lefer *et al.*, 1993), whereas enterocytes have a reduced capacity to transport electrolytes and nutrients in the postischemic intestine. The parenchymal cell alterations and organ dysfunction that are associated with ischemia–reperfusion can be attenuated by administration of NO-donating compounds or by L-arginine. There are other reports, however, that describe an improved organ function after treatment with NOS inhibitors, suggesting that NO accumulation contributes to the organ dysfunction associated with ischemia–reperfusion. Whether these different responses to NO manipulation reflect different contributions of cNOS versus iNOS to the organ dysfunction remains unclear.

Conclusion

Ischemia–reperfusion leads to an increased production of oxygen radicals, endothelial cell injury, leukocyte infiltration, and organ dysfunction. Nitric oxide bioavailability appears to be reduced in the early period after reperfusion, which is likely due to a decline in endothelial NO production and an increased inactivation of NO by endothelial cell-derived O_2^- . The limited bioavailability of NO may contribute to the abnormal cell–cell interactions and vascular dysfunction in the initial moments of reperfusion. However, as iNOS expression is increased later during reperfusion, the fluxes of NO generated by tissues is greatly increased. In some models of reperfusion injury, this increased NO flux is detrimental,

perhaps related to ONOO[−] generation. Nitric oxide-donating compounds have shown promise as protective agents in experimental models of regional ischemia–reperfusion and organ transplantation. The contradictory results obtained with NOS inhibitors in reperfusion injury models are difficult to explain. However, resolution of this issue must await a better understanding of the relative rates of production of NO and O₂[−] as well as the level of dependence of injury on leukocytes, platelets, mast cells, and macrophages in different tissues and experimental models of reperfusion injury.

Nitric Oxide: A Critical Determinant in Ischemia–Reperfusion

Allan M. Lefer

Jefferson Medical College
Thomas Jefferson University
Philadelphia, Pennsylvania*

BASAL PHYSIOLOGICAL LEVELS OF NITRIC OXIDE (NO) ARE ESSENTIAL TO THE MAINTENANCE OF CARDIOVASCULAR HOMEOSTASIS, ON THE MICRO- AND MACROCIRCULATORY LEVELS. NORMALLY, THESE PHYSIOLOGICAL CONCENTRATIONS OF NO, IN THE LOW NANOMOLAR RANGE, ORIGINATE FROM THE ENDOTHELIUM, AND THUS IT IS CALLED ENDOTHELIUM-DERIVED NITRIC OXIDE (EDNO). EDNO EXERTS A VARIETY OF IMPORTANT CIRCULATORY FUNCTIONS, INCLUDING THE MAINTENANCE OF VASODILATOR TONE, INHIBITION OF PLATELET AGGREGATION, ATTENUATION OF LEUKOCYTE ROLLING AND ADHERENCE TO THE ENDOTHELIUM, AND STABILIZATION OF ENDOTHELIAL LAYER PERMEABILITY. THE ONSET OF REPERFUSION OF AN ISCHEMIC VASCULAR BED, AS OCCURS IN MYOCARDIAL OR MESENTERIC ISCHEMIA-REPERFUSION, IN TRANSPLANTATION OF AN ORGAN (I.E., KIDNEY), OR IN REINFUSION OF SHED BLOOD FOLLOWING TOTAL BODY HEMORRHAGE, RESULTS IN A RAPID ENDOTHELIAL DYSFUNCTION CHARACTERIZED BY A LOSS OF FUNCTIONAL EDNO. THIS REDUCED EDNO LEADS TO A PROFOUND INCREASE IN EXPRESSION OF CELL ADHESION MOLECULES (E.G., P SELECTIN, ICAM-1) AND TO ENHANCED LEUKOCYTE-ENDOTHELIAL INTERACTION. THE CONSEQUENCE OF THESE EFFECTS IS MARKED STIMULATION OF THE INFLAMMATORY RESPONSE, WITH TRANSENDOTHELIAL MIGRATION OF NEUTROPHILS THROUGH THE DYSFUNCTIONAL ENDOTHELIUM TO THE AFFECTED REGION, WHERE THESE PMNs INDUCE TISSUE INJURY.

Introduction

When one markedly reduces or produces cessation of blood flow (i.e., induces ischemia) to a vascular bed and then rapidly reperfuses that vascular bed (i.e., reestablishes blood flow), a severe perturbation occurs to the organ perfused by that vascular bed. This phenomenon is known as reperfusion

injury. Reperfusion injury has been documented in several vascular beds, including those of the coronary (Van Ben-thuysen *et al.*, 1987), mesenteric (Lefer and Ma, 1991), renal (Lieberthal *et al.*, 1989), cerebral (Rosenblum *et al.*, 1992), and skeletal muscle (Korthuis *et al.*, 1988) circulations. One of the earliest and most critical events occurring after reperfusion of an ischemic bed is a marked endothelial dysfunction

characterized by the loss of endothelium-derived relaxing factor (EDRF) (Tsao *et al.*, 1990), now known to be nitric oxide (NO). This reduction in biologically active NO release has been observed in response to challenge with endothelium-dependent vasodilators [e.g., acetylcholine (ACh), A23187], the so-called agonist-mediated NO release, as well as in response to application of NO synthase (NOS) inhibitors [e.g., *N*^G-nitro-L-arginine methyl ester (L-NAME), *N*^G-monomethyl-L-arginine (L-NMMA)], which unmask the basal release of NO (Moncada *et al.*, 1990). Basal NO release is the more physiologically relevant form of NO release, but agonist-mediated NO is more widely used. Nevertheless, both indices of NO release are valid (Carey *et al.*, 1992) and are useful in quantifying the degree of endothelial dysfunction.

A dramatic and sustained endothelial dysfunction occurs following reperfusion of ischemic myocardial (Tsao *et al.*, 1990) or splanchnic vasculatures (Carey *et al.*, 1992). This endothelial dysfunction contributes significantly to the reperfusion injury of the underlying tissue, because NO promotes vasorelaxation, inhibits platelet aggregation, quenches superoxide radicals (Rubanyi and Vanhoutte, 1986; Gryglewski *et al.*, 1986), and attenuates the adherence of polymorphonuclear (PMN) leukocytes to the endothelium (McCall *et al.*, 1988; Kubes *et al.*, 1991). The endothelial dysfunction occurring in ischemia–reperfusion is characterized by a rapid decrease in biological activity of NO released from the affected endothelium. This profound decrease in NO activity

is an important event that signals early pathophysiological changes and serves as the hallmark of the first phase of reperfusion injury, termed the endothelial trigger. This endothelial trigger initiates a cascade of major pathophysiological events in reperfusion injury, and it directly leads to a second major event resulting in tissue injury (Lefer and Lefer, 1993). This second major event, which is directly dependent on the endothelial dysfunction, is known as the neutrophil amplification step. This relationship was observed initially in splanchnic ischemia–reperfusion (Bulkley, 1989), but it clearly pertains to myocardial ischemia–reperfusion and to that ischemia–reperfusion occurring in other regional vascular beds (e.g., renal, cerebral) (Lieberthal *et al.*, 1989; Rosenblum *et al.*, 1992). This two-stage sequence also occurs in total body ischemia–reperfusion such as that occurring in hemorrhage and reinfusion (Wang *et al.*, 1993) and to some extent in endotoxemia and sepsis (Siegfried *et al.*, 1992a; Wang *et al.*, 1995). Figure 1 is a time course of ischemia–reperfusion showing the temporal relationships among endothelial dysfunction, leukocyte adherence, neutrophil infiltration, and tissue injury. These relationships, which are discussed in more detail in the next section, occur not only in myocardial ischemia–reperfusion (Tsao *et al.*, 1990) but also in mesenteric ischemia–reperfusion (Hayward and Lefer, 1998a), in hemorrhage–reperfusion (Scalia *et al.*, 1999), and in trauma (Scalia *et al.*, 1996).

Figure 1 Time course of key mileposts in feline myocardial ischemia–reperfusion: onset of effects in percentage of maximal effect versus time following reperfusion of the 90-min occluded LAD coronary artery. Endothelial dysfunction was tested in isolated coronary artery rings (vasorelaxation response to acetylcholine). P-selectin expression was analyzed immunohistochemically. PMN adherence [i.e., autologous polymorphonuclear (PMN) leukocytes] to the coronary endothelium was measured in isolated coronary artery segments. PMN infiltration was studied histologically, and cardiac necrosis was assessed by nitroblue tetrazolium staining.

NO and the Endothelium in Ischemia–Reperfusion

Time Course of NO Changes in Ischemia–Reperfusion

The time course of loss of endothelial-derived nitric oxide (EDNO) in ischemia–reperfusion is well established (Tsao *et al.*, 1990). The first complete study of this type was reported by Tsao *et al.*, (1990) in myocardial ischemia–reperfusion in cats. Cats were subjected to 90 min of complete occlusion of the left anterior descending (LAD) coronary artery followed by either no reperfusion (i.e., 0 min) or reperfusion of 2.5, 5, 10, 20, 60, 180, and 270 min. LAD coronary artery rings were challenged with two endothelium-dependent vasodilators: ACh, a receptor mediated endothelium-dependent dilator, and A23187, a non-receptor-mediated endothelium-dependent dilator. Responses to these vasodilators were compared to an endothelium-independent dilator, sodium nitrite (NaNO_2) at pH 2.0. These vasorelaxant responses were also compared to those obtained with these same three vasodilators in the nonischemic control left circumflex coronary (LCX) artery. In nonischemic LCX arteries, there was a complete vasorelaxation response (i.e., 90–100%) to all vasodilators. Surprisingly, total occlusion of the LAD for 90 min in the absence of reperfusion did not diminish the vasorelaxant response to either ACh or NaNO_2 . However, 90 min of ischemia followed by only 2.5 min of reperfusion markedly attenuated the vasorelaxation response to ACh and A23187, but not to NaNO_2 . This pattern of response (i.e., attenuated relaxation to an endothelium-dependent dilator but normal relaxation to an endothelium independent dilator) is characteristic of “endothelial dysfunction” and is a consequence of the reduced NO release by the affected endothelium. Over the remaining postreperfusion time (i.e., 5 to 270 min) the vasorelaxation response to ACh and A23187 diminished further, but at no time was there a reduction in the vasorelaxant response to NaNO_2 . Therefore, endothelial dysfunction commenced in the first 2.5 min of reperfusion, and it was exacerbated and sustained over the entire 4.5-hour postreperfusion observation period. Intravenous administration of recombinant human superoxide dismutase (hSOD) just prior to reperfusion prevented much of the endothelial dysfunction (Tsao *et al.*, 1990). Thus, endothelial dysfunction was observed in response to agonist-mediated NO release by the endothelium (i.e., pulsed release).

The endothelium, however, normally releases NO continuously at low concentrations (i.e., basal release). Basal release is more difficult to quantify, but it can be done by measuring the degree of vasoconstriction of vascular rings in response to a NOS inhibitor (e.g., L-NMMA, L-NAME). Using this technique, vasoconstriction of cat LAD coronary arteries to L-NAME was found to be markedly diminished 5 min postreperfusion following 90 min of ischemia (Ma *et al.*, 1993). The response was significant at all postreperfusion times from 5 to 270 min, just as in the case of reduced ACh and A23187 responses. Thus, the endothelial dysfunction

occurring following reperfusion of an ischemic coronary vasculature can be observed both in agonist-mediated (i.e., pulsed release of NO) and in basal release of NO (i.e., low level continuous release of NO). This concordance provides strong evidence that decreased NO release is an important early consequence of postischemic reperfusion.

Additional important information on the mechanism of the endothelial dysfunction was obtained in isolated rat hearts perfused with Krebs–Henseleit buffer rather than with blood (Tsao and Lefer, 1990). Hearts were subjected to total cessation of coronary flow for 20 min followed by reperfusion (for periods of 2.5 to 45 minutes) with Krebs–Henseleit solution gassed with a mixture of either 95% O_2 plus 5% CO_2 or 95% N_2 plus 5% CO_2 . Additionally, superoxide radical release in these hearts was determined by chemiluminescence. As expected, there was a profound endothelial dysfunction 2.5 min following reperfusion with oxygenated Krebs–Henseleit buffer characterized by markedly attenuated vasorelaxation of the coronary microcirculation to ACh but not to the direct vasodilator nitroglycerin (NTG). This endothelial dysfunction gradually worsened over the ensuing 45-min postreperfusion period. This could be attributed to the large pulse of superoxide radical observed in the ischemic–reperfused vasculature within the first minute of reperfusion and which lasted for about 1 to 2 min. This burst of superoxide radical generation preceded the endothelial dysfunction and, in the absence of blood cells in the perfusate, appeared to be produced by the endothelium itself. Moreover, infusion of recombinant hSOD, but not the hydroxyl radical scavenger *N*-(2-mercaptoacetyl)-2-glycine (MPG), given at the time of reperfusion, abolished both the pulse of superoxide release, and the endothelial dysfunction.

An important follow-up finding in this study was that reperfusion with 95% N_2 plus 5% CO_2 abolished both the superoxide release and the subsequent endothelial dysfunction, clearly pointing to reoxygenation (i.e., reintroduction of oxygen) as a major factor responsible for the endothelial dysfunction. In additional studies, it was determined that myocardial ischemia–reperfusion in intact rats results in a comparable degree of coronary microvascular endothelial dysfunction as observed in isolated perfused rat hearts (Tsao and Lefer, 1991). Moreover, the time course of onset of endothelial dysfunction observed in myocardial ischemia–reperfusion in cats and rats is not unique to the coronary circulation, but is very similar to comparable events occurring in the mesenteric vasculature. Thus, splanchnic artery occlusion–reperfusion also results in a profound endothelial dysfunction in the superior mesenteric artery (SMA) of the rat (Lefer and Ma, 1991, 1993), occurring as early as 2.5 min postreperfusion and progressing to its maximal state by 60 min postreperfusion (Lefer and Ma, 1993). A comparable profile of endothelial dysfunction has been observed in cats subjected to splanchnic artery occlusion–reperfusion (Carey *et al.*, 1992; Karasawa *et al.*, 1991), and thus neither the splanchnic nor the myocardial endothelial dysfunction is species specific.

In summary, a severe form of endothelial dysfunction occurs within the first 5 min after reperfusion of the ischemic coronary or mesenteric circulation. This endothelial dysfunction is characterized by a reduced release of NO, assessed either by agonist stimulation or by basal release. The trigger event most likely responsible for the endothelial dysfunction is rapid reoxygenation of the previously ischemic vasculature, resulting in a burst of superoxide radicals that inactivate NO, and that perhaps may damage the NO biosynthetic process. Evidence suggests that a deficit in or sequestration of either tetrahydrobiopterin (TB₄), a cofactor for NO biosynthesis, or L-arginine (Hayward and Lefer, 1998b; Weyrich *et al.*, 1992; Tiefenbacher *et al.*, 1996) may be a key factor in bringing about the endothelial dysfunction (Tiefenbacher *et al.*, 1996).

One of the key aspects contributing to ischemia–reperfusion injury is the contribution of neutrophils (i.e., PMN leukocytes). Their contribution is multifaceted and clearly amplifies the reperfusion injury. Although not widely appreciated, PMNs also contribute to endothelial dysfunction under conditions of reperfusion injury. Figure 2 illustrates these principles in isolated cat coronary artery rings bathed with PMNs under a variety of conditions. When PMNs are added to the solution bathing a coronary artery ring (Fig. 2A), no vasoactive effect is observed until the PMNs are activated by a chemotactic agent (e.g., leukotriene B₄, LTB₄). On activation, the PMNs induce a significant vasocontraction of the vascular smooth muscle in the coronary artery ring. This vasocontraction is well sustained, but it can be further aug-

mented by addition of other vasoconstrictors including the thromboxane-mimetic (U-46619). Addition of ACh to the fully contracted ring produces only a very small (i.e., <10%) vasorelaxation, in contrast to a 100% vasorelaxation in response to acidified NaNO₂. This verifies the severe endothelial dysfunction.

The remainder of the recordings (Fig. 2B–E) are used to elucidate the mechanism of this PMN induced vasocontraction and related endothelial dysfunction. In Fig. 2B, employing a coronary artery ring that is de-endothelialized (–Endo), neither the vasocontraction nor the endothelial dysfunction occurs in response to activated PMNs. This suggests that the endothelium is essential for these phenomena. Figure 2C illustrates the importance of PMN interaction with the endothelium for triggering these phenomena. Thus, if one blocks PMN adherence to the endothelium with a monoclonal antibody (MAb) to CD18, the β -chain of the β_2 -integrins (i.e., the major adhesion molecule of the neutrophil), neither the PMN-induced vasocontraction nor the endothelial dysfunction occur. This experiment shows the essential nature of PMN adherence to the endothelium to provoke these phenomena. In Fig. 2D, the importance of superoxide radicals to the vasocontraction and endothelial dysfunction is unmasked, since introduction of recombinant hSOD, an enzyme which inactivates superoxide radicals, blocks both of these phenomena. Finally, in Fig. 2E, we see the critical importance of nitric oxide to these events. Inhibition of nitric oxide synthase with L-NAME produces a marked vasocontraction comparable to that induced by activated PMNs.

Figure 2 Representative recordings of isolated cat LAD coronary artery rings in isolated muscle baths at 37°C in Krebs–Henseleit buffer. Calibrations for developed force (1 g) and time (10 min) are shown. ACh, acetylcholine; LTB₄, leukotriene B₄; U46619, 9,11-methanoepoxy-PGH₂; NaNO₂, acidified sodium nitrite; MAb 15.7, anti-CD18 monoclonal antibody; ISO, isoproterenol; PMN, polymorphonuclear leukocytes; –Endo, de-endothelialized; L-NAME, N^G-nitro-L-arginine methyl ester.

This is verified by the lack of response to ACh, but not to isoproterenol (ISO), a nonendothelium dependent vasodilator. However, in this milieu lacking NO, activated PMNs fail to induce either the vasoconstriction or augment the endothelial dysfunction usually observed in response to activated PMNs.

Integrating all these findings into a sequence of events, one can see that activated PMNs adhere to the endothelium, where they release superoxide radicals which then quench basal NO continuously produced by the endothelium. This shift in balance toward superoxide and away from NO contracts the subjacent vascular smooth muscle, reflecting the loss of NO that acts as a vasodilator counteracting the basal tone of the vascular smooth muscle. Superoxide radicals are released from the activated adhered PMNs, where they can quench EDNO. If the endothelium is removed, injured, or is inhibited from producing NO, activated neutrophils cannot exacerbate the existing endothelial dysfunction. This model is a microcosm of ischemia–reperfusion injury, and it reflects many of the key elements in the pathophysiology of reperfusion injury (Lefer and Lefer, 1996). Moreover, it shows how physiological amounts of NO are important in preserving vascular homeostasis and maintenance of control of vascular tone.

Role of NO in Modulating Cell Adhesion Molecules

Considerable evidence has accumulated showing that NO attenuates leukocyte–endothelium interaction (i.e., inhibits adherence of leukocytes to the endothelium). Among the earliest evidence obtained in this area is that NO inhibits formylmethionylleucylphenylalanine (fMLP)-induced PMN aggregation (McCall *et al.*, 1988). Kubes *et al.* (1991) later showed that superfusion with L-NMMA, a NOS inhibitor, over the cat mesenteric microvasculature resulted in a dramatic increase in leukocyte adherence to the microvascular endothelium. This enhanced adhesiveness was overcome by a monoclonal antibody directed against the leukocyte β_2 -integrin CD18, the major neutrophil adhesion molecule responsible for firm cellular adhesion. This was further investigated by Davenpeck and colleagues (Davenpeck *et al.*, 1994a,b; Gauthier *et al.*, 1994), who clearly showed that suppression of endogenous NO synthesis either by pharmacological inhibition of NOS or by splanchnic ischemia–reperfusion results in increased leukocyte rolling along and adherence to the endothelium. In an elegant series of studies of intravital microscopy coupled with immunohistochemistry, this was largely attributable to upregulation of P-selectin on the affected endothelium in the absence of EDNO.

Additional evidence has since been obtained in the coronary vasculature. In a series of studies employing nitric oxide donor agents, Siegfried and co-workers (Siegfried *et al.*, 1992b,c; Johnson *et al.*, 1990) showed that several different types of NO donor agents (e.g., sydnonimine, cysteine, nitrate) inhibited the release of superoxide radicals by cat neutrophils, resulting in a NO-sparing effect on the vascular endothelium (Carey *et al.*, 1992). This maintenance of endothelium-derived NO led to a marked attenuation of my-

ocardial necrosis (i.e., less severe reperfusion injury). This suppression of free radical release has also been found in human neutrophils in the case of superoxide (Clancy *et al.*, 1992; Moilanen *et al.*, 1993) and hydrogen peroxide (H_2O_2) (Forslund and Sundqvist, 1995). These data strongly point toward an important antineutrophil effect of NO, although they do not identify the specific cell adhesion molecules involved in this phenomenon.

One interesting question being answered now is which cell adhesion molecules are downregulated by nitric oxide. In this regard, either NO donor agents or the NO precursor L-arginine decreased basal intracellular adhesion molecule-1 (ICAM-1) surface expression (Lefer *et al.*, 1993a) in cultured human aortic endothelial cells (HAECs). DeCaterina *et al.* (1995) showed that NO donor agents also downregulate mRNA and protein expression for ICAM-1 and vascular cell adhesion molecule-1 (VCAM-1) in cultured human endothelial cells. Downregulation of these important endothelial cell adhesion molecules was linked to inhibition of the transcription factor NF- κ B and can be triggered by oxidized low density lipoproteins (oxo-LDL) (Liao *et al.*, 1995). Along these lines, Armstead *et al.* (1996) reported that NO donor agents or L-arginine downregulated the mRNA and protein expression of P-selectin in human cultured iliac artery and vein endothelial cells. Moreover, L-NAME upregulated P-selectin expression in these same cell types. These studies conducted in cultured human endothelial cells are important in understanding the cell signaling mechanisms responsible for the regulatory effects of NO on cell adhesion molecules. However, they do not yield critical information on whether these interactions pertain to the intact animal under physiologically relevant conditions. To answer these questions, studies have been conducted *in vivo* employing techniques such as intravital microscopy and flow cytometry. These have been mentioned earlier (Davenpeck *et al.*, 1994a,b; Gauthier *et al.*, 1994), and coupled with immunolocalization of cell adhesion molecule expression on the microvascular endothelium, they provide powerful reinforcement of the concept that NO functionally suppresses endothelial cell adhesion molecule expression, ablating much of the leukocyte–endothelium interaction occurring soon after the onset of reperfusion.

Role of NO in Endothelial Dysfunction and Neutrophil-Mediated Tissue Necrosis

Since endothelial dysfunction is the hallmark of the early events following reperfusion of a previously ischemic vasculature, it clearly is a crucial event in reperfusion injury. This applies to the coronary, the mesenteric, and other circulations. As mentioned earlier, the key event in this endothelial dysfunction is a loss of endothelial derived NO. One of the major triggers of endothelial dysfunction is a large early burst of superoxide radicals. This early superoxide burst is thought to originate from the hypoxic–reoxygenated

endothelium itself (Zweier *et al.*, 1987). This “endothelial trigger” sensitizes the microvasculature for the consequences of endothelial dysfunction, since superoxide is known to quench NO (Rubanyi and Vanhoutte, 1986; Gryglewski *et al.*, 1986) and thus inactivate EDNO. One of the likely generators of the endothelial superoxide is the xanthine oxidase system (Bulkley, 1989). Endothelial production of superoxide anions is an important event in early endothelial dysfunction, usually occurring within the first minute of reperfusion (Tsao *et al.*, 1990; Tsao and Lefer, 1990; Lefer *et al.*, 1990). This early loss of NO is necessary but not sufficient by itself to induce profound tissue injury. In the isolated perfused cat heart, made globally ischemic and then reperfused with and without neutrophils, about 25% of the endothelial dysfunction occurs in the absence of neutrophils, and 75% of the dysfunction occurs on perfusion with activated PMNs (Tsao *et al.*, 1992). These data are consistent with the findings of Tsao and Lefer (1990) showing that PMNs play a key role in propagating the endothelial dysfunction and in contributing to the cell injury of the underlying parenchymal cells (i.e., cardiac myocytes in the case of myocardial ischemia–reperfusion, and liver and intestinal cells in the case of splanchnic ischemia–reperfusion).

A further aspect of the interaction of PMNs with endothelium-derived NO in the setting of ischemia–reperfusion is the interesting effect the oxidative burst of neutrophils has on residual NO from the dysfunctional endothelium. This large secondary burst of superoxide from activated PMNs blocks any further release of NO from the endothelium, and it results in a vasospasm-like contraction of coronary arteries (Ma *et al.*, 1991; Ohlstein and Nichols, 1989). As mentioned earlier, results obtained in both cat (Ma *et al.*, 1991) and rabbit (Ohlstein and Nichols, 1989) coronary arteries clearly show that activated PMNs induce a marked and sustained vasoconstriction in isolated arterial segments. The basis for this constriction, somewhat analogous to a coronary vasospasm, is that the PMNs activated by fMLP or by leukotriene B₄ (LTB₄) release an oxidative burst of superoxide radicals, which antagonize the basal release of NO by the endothelium (see Fig. 2). This vasospasm does not occur in an artery denuded of endothelium or when the PMNs are not activated, indicating that the vasoconstriction is clearly due to the superoxide released by activated PMNs acting on endothelium-derived NO (EDNO). This vasoconstriction can be washed out, and the arteries can be tested for their ability to relax to endothelium-dependent dilators (e.g., acetylcholine).

Similar results were obtained on activation of the endothelium, namely, with thrombin or hydrogen peroxide, without activating the PMNs (Murohara *et al.*, 1994). In this model of endothelial dysfunction, either the thrombin or the H₂O₂ upregulated P-selectin and promoted the adherence of unstimulated autologous PMNs to this activated cat coronary endothelium, despite the fact that the PMNs were normal and unstimulated. The result is a vasoconstriction followed by a marked endothelial dysfunction (i.e., attenuated vasorelaxation to ACh, but not to acidified NaNO₂). Monoclonal antibodies directed against either P-selectin (PB1.3) or

L-selectin (DREG-200), but not non-neutralizing control isotype antibodies, blocked both the vasoconstriction and the endothelial dysfunction. Additionally, a sialyl Lewis^x oligosaccharide (i.e., a selectin antagonist), but not its nonsialylated analog, also attenuated both phenomena. Coupled with flow cytometry of cultured cat endothelial cells, these results were found to be largely due to the activation of endothelial P-selectin subsequent to loss of EDNO. The PMN–endothelium interaction mediated largely by P-selectin leads to the release of superoxide radicals (Guo *et al.*, 1994). Recombinant hSOD abolished these phenomena, as did denudation of the endothelium, as in the case of the vasospasm and endothelial dysfunction induced by activated PMNs. Interestingly, a platelet activating factor (PAF) receptor antagonist (WEB-2170) also blocked these thrombin- and H₂O₂-induced vasospastic phenomena. This is not surprising because PAF is coexpressed with P-selectin on the vascular endothelium and contributes to PMN capture (Lorant *et al.*, 1991). Thus, either activating PMNs or activating the endothelium can bring about neutrophil–endothelium interaction that promotes severe endothelial dysfunction and vasospasm. Moreover, blockade of adherence of PMNs to the coronary endothelium with a neutralizing monoclonal antibody directed against either ICAM-1 (Ma *et al.*, 1992) or P-selectin (Weyrich *et al.*, 1993) or with an antiselectin oligosaccharide (Buerke *et al.*, 1994) preserves vascular endothelial function as well as attenuates myocardial injury on reperfusion. Moreover, critical reductions in basal NO release to the coronary vascular endothelium were shown to promote PMN adhesion to the ischemic–reperfused endothelium (Ma *et al.*, 1993). Thus, preservation of endogenous NO in the coronary vascular endothelium is a salient feature of the protection against reperfusion injury in myocardial ischemia–reperfusion.

One of the key mechanisms of propagation of reperfusion injury is the marked effect reduced EDNO exerts on the expression of endothelial cell adhesion molecules (CAMs). Thus, when biologically effective NO is reduced in the first 2.5 to 5 min after reperfusion of an ischemic vascular bed, expression of important endothelial cell adhesion molecules occurs rapidly. Thus, P-selectin is markedly upregulated on the endothelial cell surface within 10 to 20 min. ICAM-1, which is constitutively present on the endothelium, is upregulated more slowly (DeCaterina *et al.*, 1995; Weyrich *et al.*, 1995). Figure 3 illustrates these principles for P-selectin. In this regard, most P-selectin is usually contained within Weibel–Palade (WP) bodies located within endothelial cells (i.e., about 90% of the P-selectin is normally internalized). However, about 50% of the P-selectin can be translocated to the endothelial cell surface in 10–20 min by ischemia–reperfusion (Weyrich *et al.*, 1993, 1995). Stimuli that promote translocation of P-selectin to the endothelial cell surface are superoxide radicals, which act via conversion to H₂O₂, histamine, and thrombin. Once P-selectin is expressed on the surface of the endothelial cell, it can interact with its high affinity ligand P-selectin glycoprotein ligand-1 (PSGL-1), which is located constitutively on the microvilli of PMNs, to effect the slowing down and rolling (i.e., primary capture) of

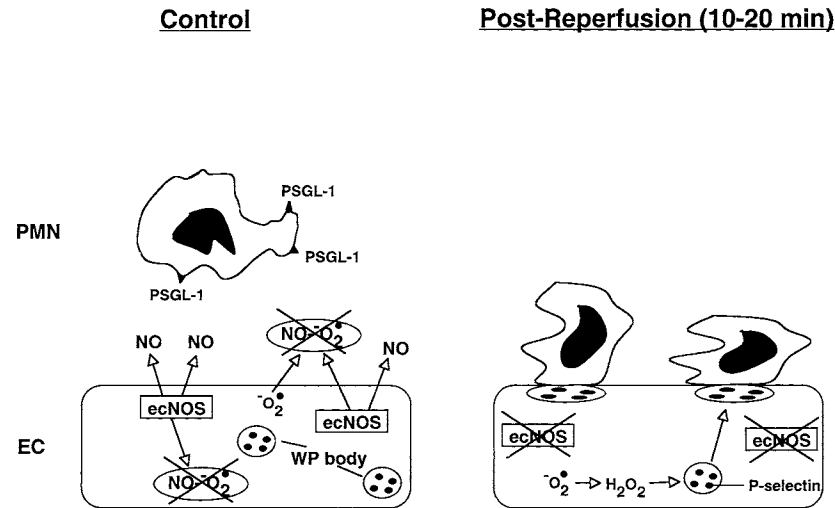

Figure 3 Scheme for explaining the postreperfusion upregulation of P-selectin on the endothelial cell surface. PMN, polymorphonuclear leukocytes; EC, endothelial cells; WP body, Weibel–Palade body; O_2^- , superoxide radicals; ecNOS, endothelial constitutive nitric oxide synthase (black dots inside WP bodies and at cell surface are molecules of P-selectin); PSGL-1, P-selectin glycoprotein ligand-1; H_2O_2 , hydrogen peroxide. When NO is quenched by superoxide radicals and H_2O_2 is formed, WP bodies translocate to the EC surface, where they bring P-selectin in contact with its PMN high-affinity ligand PSGL-1, facilitating PMN adherence to the endothelium.

leukocytes by the endothelium (Moore *et al.*, 1995). This starts the cascade of PMNs adhering to the endothelium and eventually migrating across the endothelium to the subjacent parenchymal cells (i.e., cardiomyocytes or intestinal cells), whereupon they can degranulate and release toxic mediators which injure or kill these parenchymal cells. A soluble PSGL-1 protein was found to markedly attenuate leukocyte–endothelium interaction in the rat mesenteric microvasculature following traumatic shock (Scalia *et al.*, 1999). These results point toward a key role of NO in this early response system.

icals (Rubanyi and Vanhoutte, 1986; Gryglewski *et al.*, 1986; Stewart *et al.*, 1988), and attenuation of leukocyte adherence to the endothelium (McCall *et al.*, 1988; Kubes *et al.*, 1991; Davenpeck *et al.*, 1994a,b; Gauthier *et al.*, 1994; Gaboury *et al.*, 1993). These effects occur at low nanomolar concentrations (i.e., 1 to 10 nM), which are even below concentrations of NO necessary to produce vasodilation (Davenpeck *et al.*, 1994a,b; Gauthier *et al.*, 1994; Gaboury *et al.*, 1993).

Table I summarizes the type of humoral agents that can directly release NO or promote synthesis of NO by the endothelium. In ischemia–reperfusion, authentic NO gas dis-

in Ischemia–Reperfusion**

Nitric oxide is one of the major endogenous humoral agents that is important in preserving microvascular homeostasis and preventing reperfusion injury. Nitric oxide is normally produced in low nanomolar concentrations by the vascular endothelium (Kelm and Schrader, 1990). NO can diffuse to the basilar surface of the endothelial cells and then on to vascular smooth muscle cells, where it promotes vasorelaxation of the vascular smooth muscle cells (i.e., vasodilation). NO can also diffuse to the luminal surface of the endothelium, where it interfaces with the blood and can nitrosate circulating substances such as glutathione and serum albumin (Stamler *et al.*, 1992). NO can be later released by these carriers, whence it is able to exert several important physiological actions including inhibition of platelet aggregation (Radomski *et al.*, 1991), quenching of superoxide rad-

Table I Modes of Augmenting Nitric Oxide in Biological Systems

1. Authentic nitric oxide
a. NO gas in physiological solution
b. Inhaled NO
2. NO donating substances
a. Inorganic NO releasing agents (e.g., acidified NaNO_2)
b. Classic NO donor agents (e.g., nitroglycerin, sodium nitroprusside)
c. Newer NO donor agents (e.g., sydnonimines, furoxans, NO NOates)
d. Peroxynitrite as a NO donor agent (concept of nitrosothiols as NO carriers)
3. Stimulators of NO biosynthesis
a. L-Arginine
b. Tetrahydrobiopterin
4. Gene therapy
Local ecNOS or iNOS administration
5. Agents that stabilize ecNOS mRNA
HMGCoA reductase inhibitors (e.g., simvastatin)

solved in physiological solutions (e.g., 0.9% NaCl), yielding local NO concentrations of 2 to 10 nM, has been shown to exert protective effects both in myocardial ischemia–reperfusion (Johnson *et al.*, 1991) and in splanchnic ischemia–reperfusion (Aoki *et al.*, 1990). Inhaled NO gas at 20–80 ppm has been found to exert antiadhesive effects and protect distant microvascular beds following ischemia–reperfusion (Fox-Robichaud *et al.*, 1998). The major effect was an attenuation of tissue injury and improved biochemical sequelae. In the case of myocardial ischemia–reperfusion, this was related to reduced neutrophil infiltration into the reperfused myocardium (Johnson *et al.*, 1991). These results were first observed following the administration of the inorganic NO-releasing agent NaNO₂ at pH 2.0 (Johnson *et al.*, 1990). These were the earliest reports that addition of physiological amounts of NO could exert beneficial effects in severe life-threatening forms of ischemia–reperfusion. However, these agents require significant improvement and a more readily controlled delivery system in order to be clinically useful in situations such as ischemia–reperfusion and shock.

The next major advance occurred with the synthesis of second and third generation organic NO donor agents. These are organic nitrates that release NO in solution, and they are much more potent than classic NO donor agents (e.g., nitroglycerin, nitroprusside), in addition to inducing much less “tolerance” than these agents (i.e., less tachyphylaxis). Also, these newer types of NO donor agents are more stable compounds, and they do not release superoxide radicals or cyanide, as do some of the earlier NO donors [e.g., 3-morpholinosydnonimine (SIN-1)]. Several of these newer NO donor agents have been carefully studied in myocardial ischemia–reperfusion. In this regard, C87-3754, a sydnonimine NO donor, but not its non-NO-releasing control compound C88-3934, markedly protected the ischemic cat myocardium from necrosis and preserved the integrity of the coronary vascular endothelium (Siegfried *et al.*, 1992b). Another different class of NO donor agent, a cysteine analog SPM-5185, was very effective in the same cat model of myocardial ischemia–reperfusion (Siegfried *et al.*, 1992c). In this latter study, the major mechanism of the cardioprotection was identified as inhibition of neutrophil–endothelium interaction and subsequent release of superoxide by activated PMNs (Siegfried *et al.*, 1992c). This finding was subsequently confirmed using the same NO donor agent in dogs (Lefer *et al.*, 1993b) and using a furoxan NO donor agent in isolated rat hearts perfused with PMNs (Pabla *et al.*, 1996). In both cases, nondonating control compounds having the same organic chemical backbone but lacking the NO moiety failed to exert a cardioprotective effect.

The same principles apply to splanchnic ischemia–reperfusion because the sydnonimine C87-3754 also protected cats subjected to splanchnic artery occlusion–reperfusion (Carey *et al.*, 1992). This NO donor agent increased survival and attenuated the formation of a myocardial depressant factor (MDF) (Lefer, 1987) in this lethal form of shock. Interestingly, the NO donor agent preserved the integrity and function of the superior mesenteric arterial endothelium

(Carey *et al.*, 1992). In all cases, infusion of the NO donor agent occurred at a rate that did not exert any detectable effect on arterial blood pressure (i.e., was subvasodilatory). Thus, low concentrations of NO donor agents can be very effective in ischemia–reperfusion states.

The amino acid L-arginine, the precursor in the biosynthesis of NO, has been studied in myocardial ischemia–reperfusion (Weyrich *et al.*, 1992; Nakanishi *et al.*, 1992). In the same cat model of myocardial ischemia–reperfusion as that employed in the NO donor agent studies, intravenous infusion of L-arginine was shown to be effective in reducing infarct size as well as in attenuating neutrophil infiltration into the ischemic reperfused myocardium and in preserving coronary vascular endothelial function (Weyrich *et al.*, 1992). These effects were confirmed concurrently in a dog model of myocardial ischemia–reperfusion injury (Nakanishi *et al.*, 1992) and later in a rat model of traumatic shock (Hayward and Lefer, 1998b). Thus, availability of arginine may be important in maintaining endothelial NO in ischemia–reperfusion. Tiefenbacher *et al.*, (1996) showed that there is also a deficit in TB₄, a critical cofactor in the biosynthesis of NO. When TB₄ is replaced, much of the postreperfusion endothelial dysfunction is prevented.

Although there are now many published reports showing that either low doses of NO gas or NO donor agents or infusions of L-arginine or TB₄ are protective in ischemia–reperfusion (Tsao *et al.*, 1990; Gauthier *et al.*, 1994; Siegfried *et al.*, 1992b,c; Johnson *et al.*, 1990; Lefer *et al.*, 1993b; Pabla *et al.*, 1996), there are some dissenting studies in which NO synthase inhibitors (e.g., L-NAME) also have been reported to be protective in myocardial hypoxia–re-oxygenation models (Mathies *et al.*, 1992; Schulz and Wambolt, 1995) and in either hypoxic–re-oxygenated pigs or isolated perfused rat hearts, suggesting that NO may not be good under all conditions. It is difficult to distinguish among several possible explanations explaining these findings, including the possibility that (a) L-NAME may be cardiotoxic at high doses due to coronary constrictor or other effects, (b) NO may exert different effects in ischemia–reperfusion from hypoxia–re-oxygenation, or (c) there is cardiotoxicity in these models due to formation of peroxynitrite (ONOO[−]). However, the last potential explanation is unlikely, owing to findings showing physiologically relevant concentrations of peroxynitrite to be cardioprotective both *in vitro* (Lefer *et al.*, 1997a) and *in vivo* (Lefer *et al.*, 1997b).

Authentic ONOO[−] was added to a series of isolated perfused rat hearts to yield a local concentration of 800 nM, a concentration calculated to be comparable to biologically achievable concentrations (Lefer *et al.*, 1997a). In rat hearts subjected to ischemia for 30 min and reperfusion for 45 min, ONOO[−] had no detectable effect on left ventricular developed pressure (LVDP), *dP/dt* maximum, or coronary flow. When rat hearts were subjected to ischemia–reperfusion and perfused with rat neutrophils (i.e., PMNs), a severe reduction in LVDP, *dP/dt* maximum and coronary flow occurred. However, perfusion of ischemic–reperfused rat hearts with 800 nM ONOO[−] in the presence of PMNs resulted in a marked

amelioration of the cardiodepression observed with the pH matched vehicle for peroxynitrite (ONOO^-) (Lefer *et al.*, 1997a). Physiological concentrations of ONOO^- clearly protected the heart against post-ischemia-reperfusion-induced cardiac stunning. These results also correlated closely with reduced myeloperoxidase (MPO) activity, indicative of fewer infiltrated PMNs in the ischemic rat hearts reperfused with PMNs (Lefer *et al.*, 1997a). Thus, ONOO^- markedly attenuated accumulation of PMNs in the ischemic-reperfused rat heart, and it preserved left ventricular contractility in the face of ischemia-reperfusion with neutrophils.

These studies in isolated perfused hearts have been confirmed *in vivo* in cats subjected to myocardial ischemia-reperfusion. In these experiments, ONOO^- was infused directly into the heart to achieve a local concentration of 400–1000 nM. Under these conditions, ONOO^- significantly preserved the reperfused ischemic myocardium by 55% (Lefer *et al.*, 1997b). Figure 4 illustrates the potential cardiac cytoprotective mechanism of peroxynitrite in these studies. Basically, ONOO^- is nitrosated to nitrosogluthathione, which then releases NO that is then available to the heart. These ONOO^- -treated cats also exhibited a significant preservation of coronary endothelial function (i.e., maintained NO release) as well as attenuated PMN infiltration into the ischemic-reperfused myocardium (Lefer *et al.*, 1997b). Thus, physiologically relevant concentrations of ONOO^- (i.e., 400–800 nM) act as a cardioprotective agent in ischemia-reperfusion. Earlier studies demonstrating cytotoxic effects of ONOO^- employed peroxynitrite concentrations of 500 μM to 1.5 mM ONOO^- to produce significant cell death (Szabo *et al.*, 1996). These extremely high concentrations are unlikely to ever occur *in vivo*, since ONOO^- is formed from the equimolar combination of NO and super-

oxide radical (Pryor and Squadrito, 1995; Beckman *et al.*, 1990) and NO is present in blood at 1–10 nM (Kelm and Schrader, 1990). Even if NO levels increase by a factor of 100 to 1000, this could only yield maximal ONOO^- concentrations of 1 to 10 μM . With a half-life of <1 s, ONOO^- would probably never achieve these cytotoxic levels *in vivo*.

Another way to generate NO at the site of injury *in vivo* is to transfect animals with the NOS enzyme, so that diseased blood vessels can produce their own NO. This has been proved to be effective in rat carotid arteries in a restenosis study (von der Leyen *et al.*, 1995) in which the injured vessel was able to respond to the transfected NOS by producing significant quantities of NO, which prevented myointimal proliferation, leading to a more patent artery.

Other types of agents have been identified [i.e., 3-hydroxy-3-methylglutaryl coenzyme A (HMG CoA) reductase inhibition, “statins”], such as simvastatin, which maintain endogenous NO levels by preserving or enhancing the stability of the mRNA for endothelial constitutive NOS (ecNOS). Figure 5 summarizes these relationships. Simvastatin pretreatment 18–24 hours before ischemia-reperfusion results in protection against myocardial-reperfusion injury in rats (Girod *et al.*, 1998). This has also been reported in experimental strokes or cerebral ischemia-reperfusion in mice (Endres *et al.*, 1998). The mechanism appears to be via inhibition of the biosynthesis of mevalonic acid and geranyl pyrophosphate, metabolites of the cholesterol biosynthesis pathway that cause rapid turnover of the mRNA for ecNOS. By inhibition of mevalonic acid and geranyl pyrophosphate, there is greater stability of the mRNA for ecNOS, and NO synthesis is maintained or enhanced. The enhanced NO is cytoprotective against subsequent reperfusion injury. Laufs

Figure 4 Schematic diagram of the mechanism of the cardiac cytoprotective effects of low concentrations (i.e., 400–1000 nM) of peroxynitrite. PMN, polymorphonuclear leukocytes; EC, endothelial cells; ONOO^- , peroxynitrite. Exogenously administered ONOO^- nitrosates moieties such as glutathione to transport the ONOO^- close to its site of action, where it dissociates to free NO. The free NO can diffuse to the endothelial cell surface, where it prevents PMN adherence, and to the cardiac myocytes, where it exerts additional cytoprotective effects.

Figure 5 Schematic diagram for the mechanism of preserving NO biosynthesis by simvastatin, a HMG CoA reductase inhibitor. HMG CoA catalyzes the biosynthesis of the cholesterol precursors mevalonic acid and geranyl pyrophosphate. Both of these intermediates act on endothelial cells to destabilize the mRNA for ecNOS. By inhibiting mevalonic acid and geranyl pyrophosphate synthesis in normocholesterolemic states, NO biosynthesis is preserved, and more NO is bioavailable at the vascular endothelium. This enhanced NO protects the heart against ischemia–reperfusion injury.

et al. (1997) showed that this cytoprotective effect disappears in ecNOS gene-deleted mice, whereas Lefer *et al.* (1998) actually measured the enhanced NO release from aortic segments isolated from simvastatin-treated rats. Lefer *et al.* (1998) has shown that ecNOS gene-deleted mice develop greater myocardial reperfusion injury than wild-type mice. Thus, the evidence is accumulating that endogenous physiological NO is important in protecting the vasculature from reperfusion injury.

†The Department of Surgery (Cardiothoracic), University of California, Los Angeles, School of Medicine, Los Angeles, California

NITRIC OXIDE (NO) HAS A PLETHORA OF PHYSIOLOGICAL EFFECTS IN NUMEROUS CELL TYPES AND TISSUES OF THE BODY. NO ATTENUATES THE ACTIVATION OF NEUTROPHILS [POLYMORPHONUCLEAR LEUKOCYTES (PMNs)] AND THE PRODUCTION OF SUPEROXIDE ANIONS, THE PROCESS OF DEGRANULATION, AND THE ADHERENCE OF PMNs TO THE VASCULAR ENDOTHELIUM. THE INTERACTION BETWEEN PMNs AND THE CORONARY VASCULAR ENDOTHELIUM IS A CRITICAL FACTOR IN TRIGGERING AND PERPETUATING THE INFLAMMATORY-LIKE RESPONSES CHARACTERISTIC OF MYOCARDIAL ISCHEMIA–REPERFUSION, WHICH CULMINATE IN ENDOTHELIAL INJURY, MICROVASCULAR DEFECTS AND IMPAIRED TISSUE BLOOD FLOW, AND INFARCTION. NO ATTENUATES THE UPREGULATION OF ADHESION MOLECULES DURING BOTH THE ACUTE RESPONSE AND THE LONG-TERM RESPONSES TO MYOCARDIAL REPERFUSION MEDIATED BY TRANSCRIPTION AND PROTEIN SYNTHESIS. THESE ATTRIBUTES HAVE GENERATED GREAT INTEREST IN NO AS A THERAPEUTIC AGENT AGAINST NONSURGICAL AND SURGICAL MYOCARDIAL ISCHEMIA–REPERFUSION INJURY. ENDOGENOUSLY PRODUCED NO APPEARS TO PARTICIPATE IN AN INHERENT MODULATION OF POSTISCHEMIC INJURY. AMPLIFICATION OF ENDOGENOUSLY GENERATED NO WITH THE PRECURSOR L-ARGININE AND INCREASED TISSUE LEVELS WITH PARENTERAL ADMINISTRATION OF VARIOUS CLASSES OF NO DONOR AGENTS HAVE BEEN USED TO EFFECTIVELY REDUCE NEUTROPHIL–ENDOTHELIUM INTERACTIONS, THE ACCUMULATION OF NEUTROPHILS IN REPERFUSED MYOCARDIUM, ENDOTHELIAL DYSFUNCTION, AND INFARCTION. NO THERAPY HAS ALSO BEEN USED AS AN ADJUNCT TO CARDIOPROTECTIVE STRATEGIES IN CARDIAC SURGERY, WHERE ISCHEMIA–REPERFUSION IS LIKELY A MORE COMPLEX PROCESS. HOWEVER, EXCESS CONCENTRATIONS OF NO, OR NO IN THE ABSENCE OF CERTAIN THIOLS THAT OTHERWISE CONVERT BY-PRODUCTS OF NO (SUCH AS PEROXYNITRITE) TO MOLECULES WITH NO-LIKE CHARACTERISTICS, HAS BEEN ASSOCIATED WITH INCREASED TISSUE INJURY. THE USE OF NO IN TARGETING MYOCARDIAL ISCHEMIC–REPERFUSION INJURY WILL LIKELY INCREASE AS MOLECULAR MECHANISMS OF ITS ACTIONS ARE IDENTIFIED.

Introduction

Nitric oxide (NO), also named nitrogen monoxide, is a unique molecule characterized by diametrically opposed

chemical attributes and physiological actions on both cells and whole organs. NO is very labile in physiological systems, its existence averaging less than a second in human blood. It is rapidly bound to the heme moieties on hemoglo-

bin and guanylyl cyclase—one of its major physiological effector molecules—and is rapidly transformed to the metabolites nitrate, nitrite, and peroxynitrite. However, the physiological actions of NO go beyond its short *in vivo* presence. These physiological actions include potent vasodilation, inhibition of adhesion molecule-dependent neutrophil–endothelial cell interactions, modulation of myocardial function and metabolism, and attenuation of gene expression of inflammatory mediators and their transcription signals (i.e., via nuclear factor κ B, NF- κ B).

The consequences of the physiological actions of NO may have lasting effects, despite the short life span of NO in blood and tissues. The attenuation of postischemic injury, particularly myocardial infarction and coronary vascular endothelial dysfunction, are among the consequences of the actions of NO that have a long-range impact on the health and life span of the patient. Under some circumstances, however, NO is associated with the pathogenesis of tissue injury and dysfunction, which seems to be in contrast to its potent cardioprotective attributes. Other opposing effects are exemplified by the role of NO in mediating shock, in contrast to its cardioprotective role in ischemia–reperfusion injury. Hence, NO has been cast as both (a) a pathological mediator of hypotension and cardiac dysfunction in septic shock or hypoxia–reoxygenation and (b) a potent therapeutic agent in ischemia–reperfusion and inflammation.

Finally, NO may also have opposing physiological actions depending on its biological environment. Studies show that NO may injure cells and tissue in an acellular (*in vitro*) environment, while exerting protective effects in *in vivo* blood environments. Concepts that unify this rather schizophrenic profile of NO have not been confirmed; therefore, this dichotomy of action is unresolved. Understandably, this plurality of physiological effects has made NO a topic of considerable debate and controversy, particularly regarding its role as a therapeutic agent.

This chapter focuses on the physiological actions of NO in the setting of myocardial ischemia and reperfusion encountered as a primary disease state, and as a special condition that exists during the unique circumstances presented by cardiac surgery using cardiopulmonary bypass. Ischemia–reperfusion injury not only targets myocytes, which are the contractile units of the heart, but also targets the coronary vasculature at the conduit level (arteries and veins) and at the microvascular level (arteriole, capillaries, venules). Furthermore, injury to the coronary vasculature is intimately involved in the pathogenesis (triggering) and propagation (amplification) of ischemia–reperfusion injury, whether the injury is expressed as necrosis, contractile dysfunction, or apoptosis. This chapter will describe the pathological effects of ischemia and reperfusion on the various cells that comprise the myocardium, and it discusses how NO interacts with other mechanisms triggered by ischemia and reperfusion that would potentially lead to reversible or irreversible tissue injury without its presence.

The Pathophysiology of Ischemia–Reperfusion Injury in the Heart

Ischemia

Ischemia is defined as an imbalance in the energy supply to the heart relative to its demand. Since the heart is primarily an aerobic organ with little biochemical capacity for anaerobic metabolism, the major metabolic processes are driven by oxygen. The myocardium extracts approximately 70% or more of the arterial oxygen content under normal conditions. With a physiological upper limit of 90–95% extraction, there is little oxygen extraction reserve on which to call. An ischemic condition exists if oxygen supplied by coronary blood flow is insufficient relative to the oxygen demands at the ambient level of cardiac work. A mismatch between the oxygen delivered to the myocardium and the oxygen required to sustain a given level of work, known as the oxygen supply demand status, is created either by decreasing the coronary blood flow (supply ischemia) or by increasing the work of the heart to a level beyond that which can be supported by the amount of oxygen delivered to the myocardium. The primary factors that determine the severity of ischemia in the myocardium include (a) the quantity of collateral blood flow available from other coronary arteries supplying the myocardium undergoing ischemia, (b) the ambient oxygen demands of the myocardium, and (c) the duration of ischemia. Owing to the aerobic nature of the myocardium, physiological processes requiring energy in the form of ATP, and ultimately the ability to maintain cell viability, are attenuated in proportion to the degree of the oxygen supply/demand mismatch. Hence, during ischemia, contractile dysfunction rapidly decreases (or fails to increase in the case of demand ischemia), the intracellular ionic balance is disrupted, and cell viability is threatened. *In vivo*, cell necrosis occurs after approximately 40 min of ischemia when followed by reperfusion with unmodified blood (Reimer and Jennings, 1979). Myocardium first begins to undergo necrosis in the subendocardium because the oxygen supply/demand mismatch is greatest in this region, and necrosis progresses in a “wavefront” pattern toward the subepicardium as the duration of ischemia increases. It should be noted that this temporal pattern of necrosis was observed in reperfused hearts and therefore represents combined ischemic–reperfusion injury rather than ischemic injury alone. This pattern is not apparent in hearts that are not reperfused or are reperfused with adjunctive cardioprotective agents administered systemically or intracoronarily.

Reperfusion

Although reperfusion of the myocardium is the definitive treatment for ischemia, and is the ultimate goal of both non-surgical (coronary artery angioplasty) and surgical (coronary artery bypass surgery) revascularization procedures, reperfusion carries with it the potential for extending postis-

chemic injury to myocytes, coronary vascular endothelium, and the microvasculature (Ambrosio and Chiariello, 1991; Vaage and Valen, 1993). Reperfusion injury can be defined as the pathology that is extended, accelerated, or expressed *de novo* beyond that observed during ischemia alone, resulting from events occurring *after* restoration of blood flow. Although there has been some debate whether reperfusion injury, in fact, exists (Kloner, 1993; Opie, 1991; Przyklenk, 1997; Robicsek and Schaper, 1997), a consensus is being drawn that reperfusion is indeed a significant component of the picture of postischemic myocardial injury (Hudson, 1994) in experimental models and in humans.

It is our belief that ischemia makes the heart vulnerable to reperfusion injury after the normal blood supply has been reestablished, and that a substantial degree of injury occurs after reperfusion. In support of the concept that a significant portion of the final postischemic injury is sustained during reperfusion, several investigators (enumerated throughout this chapter) have reported an immediate recovery of contractility, a significant reduction in infarct size, an attenuation of endothelial injury, and a maintenance of ultrastructural integrity of the myocardium if the conditions of reperfusion and the composition of the perfusate are modified before normal blood supply is reestablished. This “modified reperfusion” can take the form of (a) cardioprotective agents administered either systemically before reperfusion or by intracoronary infusion at the onset of reperfusion or (b) blood cardioplegia used in cardiac surgery in which agents that modify blood components (i.e., calcium concentration, osmolality) or target components of reperfusion injury are administered during the period of cardioplegia arrest, before the previously ischemic myocardium is exposed to normal blood.

MECHANISMS OF MYOCARDIAL REPERFUSION INJURY

Among the more important mechanisms of myocardial reperfusion injury in the heart are (a) calcium influx and loss of normal intracellular calcium homeostasis, (b) oxygen radical generation, (c) neutrophil activation, release of neutrophil-derived products, and adhesion to the endothelium, and (d) production of microvascular injury characterized by interstitial edema, impaired blood flow (“no-reflow”), and defective autoregulation. These mechanisms of injury do not operate independently, nor are they mutually exclusive. However, reperfusion injury has been shown to be a malleable process that can be attenuated by applying a number of therapies targeting these various mechanisms of injury. NO is one of these important cardioprotective therapies that has emerged in the 1990s.

Neutrophils have been implicated as a player in the pathophysiology underlying nonsurgical as well as surgical ischemic–reperfusion injury. The mechanisms of neutrophil-mediated injury include (a) generation of oxygen free radicals and related oxidants [hydrogen peroxide (H_2O_2), hydroxyl radical ($\cdot\text{OH}$), hypochlorous acid (HOCl)], (b) degranulation to release myeloperoxidase that produce HOCl ,

as well as proteases or other enzymes that degrade membranous structures and components of the extracellular matrix, (c) the release of arachidonic acid metabolites [phospholipase A_2 , leukotriene B_4 (LTB_4)] and other proinflammatory mediators such as platelet activating factor (PAF) and tumor necrosis factor α ($\text{TNF-}\alpha$). These mechanisms also represent the primary targets toward which antineutrophil therapy is directed. Although superoxide anions, hydrogen peroxide, and hydroxyl radicals generated by neutrophils are important reactive oxygen species that mediate tissue damage, HOCl is the predominant cytotoxic oxidant derived from neutrophils. Its cytotoxicity results from production of powerfully oxidizing chloramines. In addition to causing direct injury to myocardium, these reactive oxygen species provide leukotactic signals by stimulating the generation of complement, by inducing expression of P-selectin on endothelium, and by inducing surface expression of PAF on endothelium.

The Coronary Vascular Endothelium, Nitric Oxide, and the Effects of Ischemia–Reperfusion Injury

Normal Physiology of Endothelium-Derived Nitric Oxide

NO is generated by endothelial-specific NO synthase (or eNOS) primarily localized in vascular endothelium, but localized also in cardiac myocytes. NO is a potent vasodilator, and it has been termed the endogenous nitrovasodilator because of its role in regulating tissue blood flow and vascular resistance. eNOS is a calcium/calmodulin-sensitive enzyme activity that is regulated by physiological concentrations of Ca^{2+} . Ca^{2+} increases the binding of calmodulin to eNOS, thereby initiating the electron flow necessary to convert the guanidino nitrogen of L-arginine to NO and L-citrulline in the presence of molecular oxygen. Tetrahydrobiopterin (TB_4) is a cofactor that facilitates the flow of electrons from NADPH to the heme moiety of eNOS. In the absence of TB_4 and L-arginine, eNOS can generate superoxide anions from the oxygenase and reductase domains of the heme enzyme.

Under basal conditions, the coronary vascular endothelium tonically releases NO (Guo *et al.*, 1996; Ma *et al.*, 1993; Engelman *et al.*, 1995a) in concentrations ranging from 0.1 to 1 nM. This basal release of NO is regulated by vascular shear stress (Buga *et al.*, 1991; Cooke *et al.*, 1990; Nerem *et al.*, 1993), by the presence of physiological agonists such as acetylcholine and bradykinin, and by the availability of the substrates L-arginine and oxygen. Vascular shear stress and associated deformation of the endothelium, both of which accompany pulsatile perfusion, activate eNOS (Stewart *et al.*, 1994; Smith and Canty, 1993). Higher shear stresses created by high blood flow in vessels stimulates eNOS activity to release greater quantities of NO, whereas low shear stress created in low-flow situations reduces the release of NO.

A number of agonists specifically stimulate the release of NO from the vascular endothelium. Acetylcholine and bradykinin trigger an increase in intracellular calcium through receptor-mediated mechanisms which, in turn, stimulates eNOS activity and the release of NO in a concentration-dependent manner. Ca^{2+} ionophores such as A23187 will also stimulate eNOS activity and the release of NO, but by receptor-independent mechanisms, which helps to differentiate receptor-dependent from receptor-independent pathways of signal transduction. This information can be used to distinguish whether receptor mechanisms or the enzyme system itself has been impaired by ischemia–reperfusion injury or other interventions. The NO released by these mechanisms induces vasorelaxation by diffusion to the vascular smooth muscle. The resultant concentration-dependent vasodilator (relaxation) responses to receptor-dependent and receptor-independent stimulators of eNOS, mediated largely by NO, form the basis of bioassay systems designed to quantify the functional state of vascular tissue *in vitro* and *in vivo*.

The generation of NO by vascular endothelium is inhibited by a number of pharmacologic agents. Guanidino-substituted L-arginine analogs such as N^G -nitro-L-arginine methyl ester (L-NAME) and N^G -monomethyl-L-arginine (L-NMMA) are effective inhibitors of eNOS activity, thereby reducing the production and release of NO into the luminal (area of blood flow) and abluminal (perivascular interstitial)

compartments. These inhibitors of eNOS are often used in both *in vitro* and *in vivo* experiments to confirm the involvement of NO in physiological situations. For example, vascular ring preparations (Fig. 1) are used to measure vascular tension in small (2–3 mm) segments of vessels excised from the heart and other organs and then placed in chambers containing physiological buffer solutions. This *in vitro* preparation may include NO synthase inhibitors in the buffer to attenuate suspected NO-induced vasorelaxation responses to endothelial-specific agonist stimulators of nitric oxide synthase activity, such as acetylcholine or bradykinin, to distinguish the action of NO from that of other endogenous vasodilator substances such as prostacyclin or adenosine. Hence, these NOS inhibitors are used to “chemically denude” vascular tissue of endothelium, again to describe the role of NO derived from the vascular endothelium.

The NOS inhibitors can also be used in organ chamber bioassay systems to qualitatively estimate the basal release of NO. Because NO is rapidly degraded in biological and *in vitro* environments, it is difficult to measure directly by electrode systems or colorimetric methods. However, the concentration-dependent vasorelaxation induced by NO in blood vessels *in vitro* can be used to advantage to provide a useful bioassay by which to indirectly estimate the production of NO by vascular endothelium. A normal coronary artery with significant basal release of NO will accordingly

Figure 1 Diagram of the organ chamber technique for measuring endothelial function in segments of coronary artery and vein. The test vessel is placed in an organ chamber filled with a nutritive buffer at 37°C, and it is connected to a force transducer that measures the force generated by the vessel as it contracts or relaxes. Vessels are precontracted with vasoconstrictor agents to give a background tension from which relaxation can be achieved. The force transducer is connected to a chart recorder or computer to display force changes. Test agonist stimulators of nitric oxide synthase or smooth muscle relaxing agents are added in incremental concentrations (arrows), which causes progressive relaxation. The percent relaxation from the precontracted force is analyzed using the force–concentration plot shown in the bottom right panel.

demonstrate a vasoconstrictor response that is proportional to the NO-induced vasodilator tone, which is withdrawn by application of NO synthase inhibitors. However, coronary artery endothelium that has sustained injury from stresses such as exposure to superoxide radicals or ischemia–reperfusion will demonstrate substantially attenuated constrictor responses to application of NO synthase inhibitors, which is indicative of an impaired basal release of NO secondary to endothelial injury. Therefore, both the vasorelaxation responses to agonist stimulators of NO and the vasoconstrictor responses to inhibitors of eNOS have been used to indirectly estimate the capacity of vascular endothelium to release NO.

Ischemia–Reperfusion Injury Leads to Endothelial Cell Dysfunction

Ischemia and reperfusion attenuate endothelial cell function. This dysfunction is expressed as attenuated basal release of NO (reduced constrictor responses to eNOS inhibitors), reduced vasodilator responses to agonist stimulators of eNOS, and a loss of its ability to prevent neutrophil adherence to the endothelial surface of coronary arteries and veins. In the absence of reperfusion, postischemic endothelial dysfunction is minimal after short-term ischemia (60–90 min) (Ma *et al.*, 1993; Tsao and Lefer, 1990), but it may be expressed after more prolonged periods of ischemia (>90 min) (Dignan *et al.*, 1992). Hence, if a period of either regional ischemia (coronary occlusion) or global ischemia were imposed and the coronary arteries excised before the onset of reperfusion, endothelial function would appear to be near normal. However, in the presence of reperfusion, endothelial dysfunction is expressed within minutes after the start of reflow, and it persists for hours (A. M. Lefer *et al.*, 1991; Tsao *et al.*, 1990) to days (Kaeffer *et al.*, 1996) after reperfusion. This dysfunction is described as a decrease in both basal and agonist-stimulated NO release and vasorelaxation and in adherence of neutrophils to the endothelium. These physiological responses are attenuated in reperfused coronary vessels roughly in proportion to the degree of injury (Dignan *et al.*, 1992; Nakanishi *et al.*, 1994; Tsao *et al.*, 1990; Tsao and Lefer, 1990).

BASAL ENDOTHELIAL FUNCTION

Under normal circumstances, the tonic or basal release of NO causes a continuous degree of vasodilation, the extent of which is dependent on the amount of NO released. This basal NO can be measured using direct methods such as NO-sensitive electrodes or methods based on the Griess reaction and similar colorimetric methods. In addition, the amount of NO release can also be estimated indirectly by observing the change in basal vascular tone when inhibitors of NO synthase activity are administered, as discussed earlier. Non-metabolized analogs of L-arginine such as L-NAME or L-nitroarginine (L-NA) inhibit NO synthase activity and reduce appreciably the amount of NO released basally (and with agonist stimulators of NO synthase). When these NO

Figure 2 Basal endothelial function described by vasocontraction responses to inhibitors of nitric oxide synthase. In a feline model of ischemia–reperfusion, the left anterior descending (LAD) coronary artery was occluded for 90 min and reperfused for a total of 270 min. At the various time points indicated on the abscissa, the coronary arteries were excised, cut into rings 2–3 mm in width, and mounted in organ chambers to measure tension. After preconstriction to a target tension, the nitric oxide inhibitor is added to the bath. Coronary artery rings will subsequently constrict in accordance with the withdrawal of NO-dependent vasodilator tone. Cont, normal control (no ischemia); R, minutes of reperfusion. Data adapted from Ma *et al.*, 1993.

synthase inhibitors are administered *in vitro*, the extent of vasoconstriction secondary to withdrawal of NO-induced vasodilator tone gives the investigator a bioassay barometer of this basal NO release. Similarly, when inhibitors are given *in vivo*, the extent of increase in local vascular resistance or the degree of hypertension observed after NO synthase inhibitor administration provides information as to the basal vasodilator tone.

In ischemia–reperfusion, tonic NO release by the coronary vascular endothelium measured directly using *in vitro* techniques is reduced in hearts subjected to ischemia–reperfusion (Engleman *et al.*, 1995a; Guo *et al.*, 1996). Commensurate with this attenuated tonic vasodilator tone, the vasocontraction observed when NO synthase inhibitors are administered *in vitro* in organ chambers is reduced owing to loss of tonic NO-dependent vasorelaxation (Ma *et al.*, 1993). This loss of basal NO-induced vasodilator tone is shown in Fig. 2. Note in Fig. 2 that in normal coronary arteries with healthy endothelium, the administration of an NO synthase inhibitor (L-NAME) to the organ chamber bath caused a brisk vasocontraction. Interestingly, after 90 min of ischemia without reperfusion, this vasocontraction is still essentially the same as in the normal coronary artery. However, with increasing durations of reperfusion, the vasocontraction is progressively lost, suggesting a progressive loss of basally released NO during reperfusion.

In addition to impaired vasocontraction responses to NO synthase inhibitors, basal endothelial function can also be assessed by quantifying the adherence of unstimulated neutrophils on the surface of test coronary arteries or veins. This method takes advantage of the potent antineutrophil effects of NO that is tonically released while segments of vessels are incubated in organ chambers or culture dishes. The adherence of unstimulated neutrophils is prevented by the tonic release of nitric oxide in normal vessels (Fig. 3). After 90

Figure 3 Adherence of unstimulated neutrophils to coronary artery endothelial surface is used as another measure of basal endothelial function. In this case, the LAD coronary artery in a feline model of ischemia–reperfusion was occluded for 90 min and reperfused for a total of 270 min. At the various time points indicated on the abscissa, the coronary arteries were excised, cut into segments and incubated with unstimulated fluorescent labeled neutrophils, and visualized under epifluorescence microscopy. Cont, normal control (no ischemia); R, minutes of reperfusion. Adapted from Ma *et al.* (1993).

min of ischemia, this ability to ward off adherence of unstimulated neutrophils to the endothelial surface is still intact. However, after reperfusion, the ability to prevent neutrophil adherence is increasingly compromised with time. Therefore, both the adherence of unstimulated neutrophils to coronary artery endothelium and the loss of basally released nitric oxide (indirectly measured by vasoconstriction responses to inhibitors of nitric oxide synthase) have been shown to progressively increase with reperfusion time, but were normal after ischemia alone (Ma *et al.*, 1993).

STIMULATED ENDOTHELIAL FUNCTION

NO synthase activity is stimulated by agonists such as acetylcholine, bradykinin, and substance P in a concentration-dependent manner. To quantify this ability of NO synthase to release NO under agonist stimulation in a bioassay system, coronary vessels (arteries or veins) are cut into segments and mounted in organ chambers, as shown in Fig. 1, and precontracted with a constrictor agent such as norepinephrine or the thromboxane A₂ mimetic U46619. Sequential addition of an agonist stimulator of NO synthase, such as acetylcholine, in incremental concentrations will elicit increasing degrees of vasorelaxation until the normal vessel relaxes completely. When coronary arteries excised from hearts subjected to regional ischemia without reperfusion are analyzed in this way, relaxation responses to acetylcholine are essentially complete (top left tracing of Fig. 4). This relaxation response to acetylcholine is NO induced, as it can be completely blocked by inhibitors of NO synthase. However, the vasorelaxation is increasingly attenuated after reperfusion, starting as early as 2.5 min. These observations suggest that endothelial dysfunction after ischemia occurs principally during reperfusion, and that this “reperfusion injury” is a dynamic process that worsens with time of reperfusion. Attenuated endothelial vasodilator responses to intracoronary

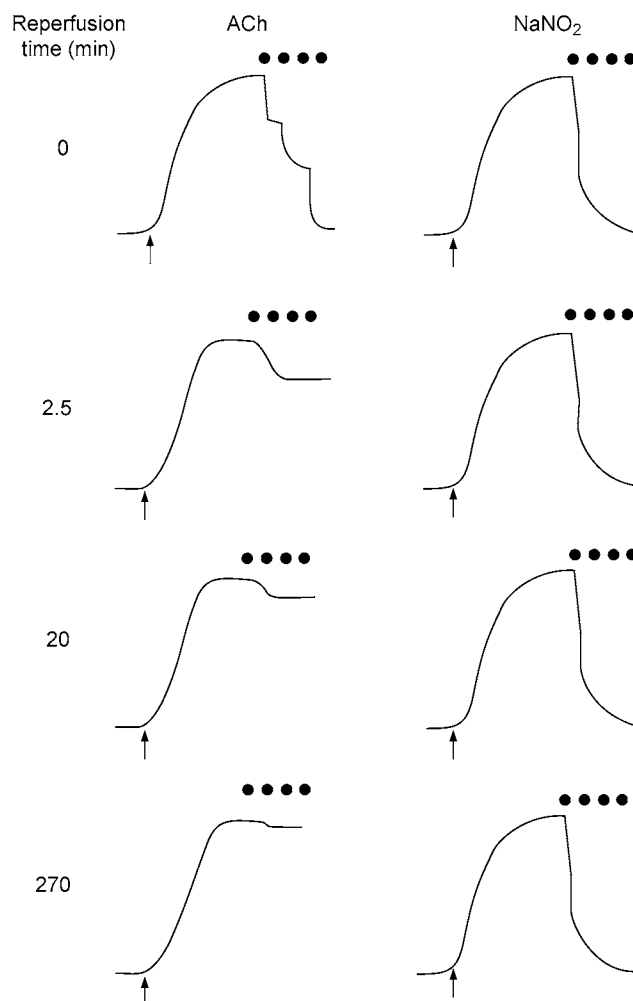

Figure 4 Vasodilator responses of coronary arteries to acetylcholine (left) and the NO donor agent acidified NaNO₂ (right) after ischemia and increasing periods of reperfusion. The dots over each tracing indicate application of respective drug. From Lefer and Scalia (1999), with permission.

acetylcholine infusions have also been reported *in vivo* (Sobey *et al.*, 1990) after coronary artery occlusion and reperfusion, and they are consistent with the *in vitro* findings using excised coronary vessels in organ chambers. This endothelial dysfunction after reperfusion is similar to the vasodilator responses to acetylcholine observed in coronary arteries with mechanical denudation of the endothelium. Morphologically, the coronary artery after 1 hour of ischemia appears normal with intact endothelium (VanBenthuyzen *et al.*, 1987). After reperfusion, the endothelium remained intact despite the significant loss of vasodilator responses to acetylcholine (VanBenthuyzen *et al.*, 1987). Therefore, endothelial dysfunction may involve a defect in the stimulation of eNOS or a biochemical defect in its activity, rather than solely a morphologic injury to the endothelial cell. Endothelial dysfunction, expressed as attenuated relaxation responses of the coronary vascular endothelium to ADP and increased adherence of unstimulated neutrophils, is also observed in coro-

Figure 5 Endothelial dysfunction in coronary veins after 60-min occlusion of the paired coronary artery followed by 120 min of reperfusion. (Left) Adherence of unstimulated canine neutrophils to nonischemic (control) and ischemic-reperfused coronary veins. (Right) vasorelaxation responses of postischemic canine coronary veins to ADP (endothelium-specific stimulator), the calcium ionophore A23187 (endothelial receptor-independent stimulator), and acidified (pH 7.2) NaNO₂ (smooth muscle dilator). From Lefer *et al.* (1992), with permission.

nary veins (Fig. 5) (D. J. Lefer *et al.*, 1992). This observation is important because venules in the ischemic–reperfused myocardium may be the site of neutrophil adherence, transendothelial migration into the myocardial tissue, and subsequent interaction with myocytes. Loss of the antineutrophil characteristics of coronary venous endothelium potentially promotes neutrophil interaction.

Endothelial dysfunction similar to that seen in regional ischemia–reperfusion is observed in models of global ischemia. Tsao and Lefer (1990) subjected isolated perfused rat hearts to 20 min of global ischemia by stopping the perfusion of Krebs–Henseleit buffer to the heart. Endothelial function was assessed by the decrease in vascular resistance and perfusion pressure in response to acetylcholine or nitroglycerin when myocardial perfusion flow rate was held constant. Reperfusion with oxygenated (95% O₂ + 5% CO₂) Krebs–Henseleit buffer was accompanied by endothelial dysfunction expressed as a decrease in vasodilator (coronary perfusion pressure) response to acetylcholine. Smooth muscle responses to nitroglycerin were not affected. Similar to the time course of endothelial dysfunction described above for regional ischemia, the extent of endothelial dysfunction was exacerbated with increasing duration of reperfusion in this global ischemic model. The endothelial dysfunction may have been caused by oxygen radicals since other sources of reactive oxygen species (i.e., neutrophils) were absent. Indeed, Tsao and Lefer (1990) noted a significant increase in superoxide radical production specifically from the endothelium, measured by chemiluminescence, in the first moments of reperfusion. Extensive studies have shown that superoxide radicals participate in the pathophysiology of endothelial dysfunction (Lefer and Lefer, 1991) and other end points such as necrosis (Lucchesi, 1994) and contractile dysfunction

(Bolli, 1988, 1991). Potential sources of superoxide radicals in this neutrophil-free environment include mitochondria, xanthine oxidase, and NAD(P)H oxidase.

The Role of Neutrophils in Mediating Postischemic Endothelial Dysfunction, Contractile Dysfunction, and Necrosis

Neutrophils have been found to be important mediators of *in vivo* reperfusion injury of the vascular endothelium, with significant consequences to the pathogenesis of necrosis (infarct size), defective regulation of blood flow and its transmural distribution, tissue edema, and contractile dysfunction. Neutrophil adherence to the coronary endothelium induces functional injury (A. M. Lefer *et al.*, 1993; Sato *et al.*, 1996, 1997a). As discussed later, NO is a very potent inhibitor of neutrophil events. Hence, a discussion of neutrophils in the pathogenesis of myocardial ischemia–reperfusion injury is germane to understanding the role of endothelial injury in NO-related therapy in attenuating this injury.

The coronary vascular endothelium plays a critical role in the pathogenesis of reperfusion injury in the myocardium (Boyle *et al.*, 1996; A. M. Lefer *et al.*, 1991, 1993; D. J. Lefer *et al.*, 1992). During the early moments of reperfusion, neutrophils are recruited to the endothelial surface in a requisite interaction between the two cell types. This interaction is mediated by a highly specific and well-orchestrated sequence of events involving the upregulation of adhesion molecules on both the endothelium and neutrophils, as summarized in Fig. 6. The initial event is characterized by skipping or “rolling” of the neutrophils along the endothelial surface, a process mediated by interaction between

Figure 6 Diagram of neutrophil–endothelial cell interactions during reperfusion with regard to phases of adherence and the principal adhesion molecules involved on the bottom of the figure. Endothelium (EC) can be activated by ischemia–reperfusion (I–R) as well, or products thereof such as superoxide anions (O₂⁻) and thrombin (Throm), causing the surface expression of P-selectin (P) from preformed Weibel–Palade bodies. This is the endothelial “trigger” phase. Neutrophils are activated by platelet activating factor (PAF), ischemia–reperfusion (I–R), the complement fragment C5a, or other stimulators. Activation of EC and neutrophils attracts the neutrophils toward the EC, to which the neutrophils first “roll” [mediated by P-selectin and L-selectin or by P-selectin glycoprotein ligand-1 (PSGL-1)] and later firmly adhere [mediated by intracellular adhesion molecule-1 (ICAM-1) on the endothelium and CD11/CD18 on the neutrophil]. Amplification of the inflammatory response occurs when activated endothelium and neutrophils release oxidants and proinflammatory mediators, which recruits more neutrophils to the site of injury. PECAM, platelet–endothelial cell adhesion molecule; SMC, smooth muscle cells; Hist, histamine; AcPAF, acylated platelet activating factor.

P-selectin on the endothelium and sialylated glycoprotein on the neutrophil, most likely the sialomucin P-selectin glycoprotein ligand-1 (PSGL-1) (McEver and Cummings, 1997; Moore *et al.*, 1995) or sialyl Lewis^x. This initial interaction is an obligatory step necessary for distal firm adherence and transendothelial migration into the myocardial parenchyma and their physiological sequelae (no-reflow, necrosis) (Davenport *et al.*, 1994a; Geng *et al.*, 1990; Jerome *et al.*, 1994; Kubes *et al.*, 1995). E-selectin on the endothelium may also interact with a sialylated glycoprotein (sialyl Lewis^x) to facilitate neutrophil rolling. After this initial loose tethering of neutrophils to the vascular endothelium mediated by P-selectin, firm adherence is facilitated by interaction of intracellular adhesion molecule-1 (ICAM-1) on the endothelium with its counterligand CD11b/CD18 on neutrophils. ICAM-1 is constitutively expressed on the endothelial surface, but is upregulated after 2 to 4 hours of reperfusion by cytokines.

After this cascade has led to firm adherence on the endothelium, the neutrophils emigrate through the endothelial layer (transendothelial migration) and accumulate in the interstitial compartment of the ischemic–reperfused myocardium. The transendothelial migration, like the adherence process itself, occurs primarily after the onset of reperfusion, but at a later stage (~4 hours) (Dreyer *et al.*, 1991a; Entman

et al., 1991; A. M. Lefer *et al.*, 1993). Dreyer *et al.* (1991a) have shown that the rate of neutrophil accumulation within the reperfused area occurs most rapidly within the first hour of reperfusion, which may represent primarily intravascular neutrophils adherent to the endothelium rather than interstitial neutrophils. Lefer *et al.* (1991) have reported a similar time course using tissue myeloperoxidase activity as a marker of neutrophil accumulation. Furthermore, Lefer *et al.* (1993) have shown that this accumulation of neutrophils in ischemic tissue is preceded first by adherence of neutrophils to the coronary vascular endothelium, followed by accumulation in the area at risk most likely secondary to transendothelial migration. The adherence of neutrophils is closely associated with the time course of endothelial dysfunction in both surgical (Byrne *et al.*, 1992; D. J. Lefer *et al.*, 1993a; Nakanishi *et al.*, 1995; Sato *et al.*, 1995a; Wilson *et al.*, 1993) and nonsurgical ischemia–reperfusion models.

The critical factor that allows neutrophils to interact with the endothelium is the stimulation of the endothelium during early reperfusion to express certain adhesion molecules. These early events act as the endothelial “trigger” of the inflammatory cascade. First, the endothelium releases a burst of superoxide radicals (Tsao and Lefer, 1990; Zweier *et al.*, 1987) in the first few minutes of reperfusion. This burst of superoxide radicals not only activates the endothelium and stimulates the expression of adhesion molecules involved in the neutrophil–endothelial cell cascade (McIntyre *et al.*, 1995), but also directly quenches NO through a biradical reaction (Gryglewski *et al.*, 1986; Rubanyi and Vanhoutte, 1986), leading to a decrease in the periendothelial concentration of NO. Second, the endothelium is activated by inflammatory mediators such as TNF- α , interleukin 6 (IL-6), thrombin, histamine, LTB₄, and complement fragments released either locally or into the systemic circulation. Complement fragments such as C3a and C5a are found in the lymph drained from the area at risk during reperfusion (Dreyer *et al.*, 1989), and they are produced locally in the area at risk (Pinckard *et al.*, 1980). Third, the interaction between neutrophils and endothelium stimulates the neutrophils directly, thereby triggering a release of reactive oxygen species (superoxide anion, hydrogen peroxide, hydroxyl radical, hypochlorous acid) and inflammatory mediators. This second phase is an amplification stage that causes further endothelial injury and increased recruitment of neutrophils to the site of injury subsequent to the initial triggering event.

Neutrophils have been shown to directly cause injury to basal and stimulated function of the endothelium. Administration of thrombin to a cocubate of neutrophils and coronary artery rings with healthy endothelium in organ chambers causes contraction of the artery, not only because of neutralization of NO by superoxide anion, but also because of impaired release of nitric oxide (Fig. 7A). Thrombin selectively stimulates the endothelium by triggering the surface expression of P-selectin, but it has no direct effect on neutrophil activation. The degree of vasoconstriction (an estimate of basal NO release) is paralleled by the number of

Figure 7 Neutrophil-induced vasoconstriction and adherence to canine coronary artery segments. (A) Vasoconstriction is measured in grams tension in organ chambers. Thrombin (2 U/ml) increases the vasoconstriction response induced by unstimulated neutrophils when they are added to the bath. This vasoconstriction is reversed by P-selectin antibody PB1.3, suggesting that adherence of neutrophils to endothelium is requisite for the induction of contraction. Other stimulators such as H₂O₂ and histamine stimulate the endothelium to increase adherence of unstimulated neutrophils, again resulting in vasoconstriction. Blockade of basal NO release with L-NA increases neutrophil-induced vasoconstriction, suggesting that this tonically released NO has important antineutrophil effects. (B) Adherence of neutrophils to thrombin-stimulated canine coronary artery endothelium. The similarity to the pattern in A suggests that adherence of neutrophils is a necessary step in producing the vasoconstriction. Reprinted from *Cardiovascular Research*, Volume 43, J. E. Jordan, Z.-Q. Zhao, and J. Vinten-Johansen, The role of neutrophils in myocardial ischemia–reperfusion injury, pp. 860–878, Copyright 1999, with permission from Elsevier Science.

neutrophils adherent to the coronary artery endothelium (Fig. 7B). In addition, the vasoconstriction responses could be attenuated by an antibody to P-selectin, PB1.3, demonstrating the dependence of P-selectin-mediated interaction on subsequent events leading to vascular endothelial injury. Furthermore, the degree of vasoconstriction after coincubation of neutrophils with endothelium is accentuated by the

NO synthase inhibitor L-nitroarginine (L-NA), again associated with an increase in neutrophil adherence.

Figure 8 shows endothelial responses to acetylcholine (endothelium-dependent stimulator) and sodium nitroprusside (endothelium-independent agonist) after incubation of unstimulated neutrophils with coronary thrombin-stimulated arterial rings. Thrombin treatment in the absence of neutro-

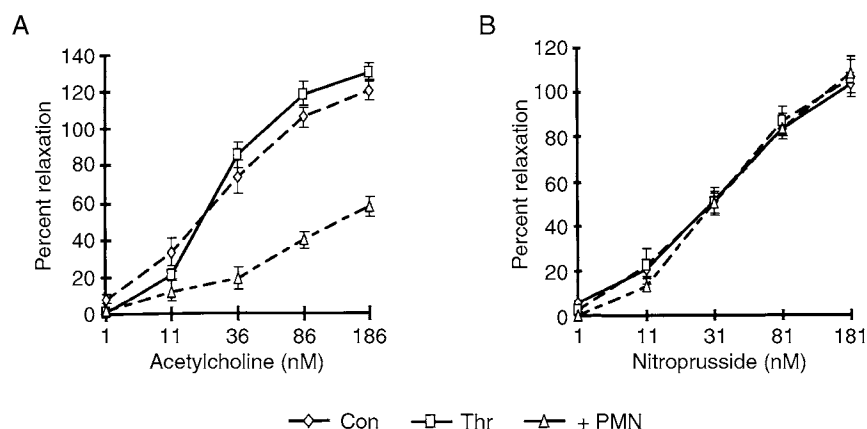

Figure 8 Vasorelaxation response to incremental concentrations of acetylcholine (A) and sodium nitroprusside (B) in thrombin-stimulated canine coronary artery rings coincubated with unstimulated neutrophils. The coronary arteries were preconstricted with the thromboxane A₂ mimetic U46619. Con, unstimulated coronary arteries; Thr, thrombin stimulated coronary arteries without neutrophils; + PMN = incubation with unstimulated neutrophils. Reprinted from *Cardiovascular Research*, Volume 43, J. E. Jordan, Z.-Q. Zhao, and J. Vinten-Johansen, The role of neutrophils in myocardial ischemia–reperfusion injury, pp. 860–878, copyright 1999, with permission from Elsevier Science.

phils induces no discernible alterations in agonist-stimulated vasorelaxation responses. In contrast, incubation of neutrophils with thrombin-stimulated coronary artery endothelium is associated with a significant decrease in the concentration–response vasorelaxation curve, with a characteristic decrease in maximal response to the highest concentration of acetylcholine used. The vasorelaxation responses to the endothelium-dependent, receptor-independent agent A23187 (not shown) demonstrated similar attenuated vasorelaxation responses, suggesting that the defect was distal to the muscarinic receptor. In contrast, vasorelaxation responses to the direct smooth muscle dilator sodium nitroprusside were complete in all treatments. Taken together, these data suggest that neutrophils induce endothelium-specific damage to receptor-dependent and receptor independent vasodilator function.

Endothelial Injury and Infarction

The coronary vascular endothelium is essentially the “front line” defense system for the myocardium. The vascular endothelium is strategically located between the intravascular (blood) compartment, with its neutrophils and circulating inflammatory mediators and the underlying myocardial parenchyma. Accordingly, NO is released into the critical locations necessary to interdict the strategic participants in the inflammatory cascade of ischemia–reperfusion injury. NO diffuses into the abluminal side in the proximity of the vascular smooth muscle, into the interstitial compartment where it is in close proximity to myocytes, and into the intravascular compartment where it exerts important physiological effects on neutrophils, endothelium, and platelets. As we discussed earlier, the endothelium is a critical factor in the neutrophil component of pathophysiological responses to ischemia–reperfusion. In addition, it is well known experimentally and clinically that ischemia–reperfusion causes injury to structures other than the endothelium. The myocyte is an obvious target of ischemia–reperfusion injury, but other targets of injury include the microvasculature and the genetic apparatus. The various manifestations of ischemia–reperfusion injury in the heart are discussed next.

ENDOTHELIAL INJURY

Endothelial injury occurs within minutes of reperfusion, and it is thought to be a critical factor in triggering and amplifying injury to the myocyte in terms of viability (necrosis) and function (contraction). Hence, there is a close association between the endothelium and myocyte in models of irreversible ischemia–reperfusion injury. However, in less severe models of ischemia causing myocardial stunning in which necrosis does not occur, therapeutic strategies toward reducing endothelial dysfunction may not predict the benefits to postischemic contractile function. In a model of 30-min left anterior descending (LAD) occlusion causing contractile dysfunction (Bufkin *et al.*, 1998), Thourani *et al.* (1999) observed that ischemic preconditioning reduced endothelial dysfunction (vasoreactive responses to acetylcholine) but failed to improve postischemic systolic or diastolic

function in the involved myocardium. More relevant to cardiac surgery using cardioplegia, Mizuno *et al.* (1997) reported that 20 min of normothermic global ischemia followed by unsupplemented blood cardioplegia was associated with no significant postischemic systolic (pressure–volume relations and Starling function curves) or diastolic dysfunction. However, there was significant endothelial dysfunction. Hence, endothelial dysfunction can occur in the absence of either contractile dysfunction or necrosis in nonlethal models of ischemia–reperfusion injury. In the study by Mizuno *et al.* (1997), 2 mM L-arginine in the blood cardioplegia solution, a concentration sufficient to increase transcardiac nitrate/nitrite production suggestive of increased NO production, reduced postischemic endothelial dysfunction, which was reversible with the NO synthase inhibitor L-NAME. Therefore, endothelial dysfunction may occur in the absence of contractile dysfunction in models of nonlethal injury, and recovery of endothelial function (with NO therapy or other cardioprotective therapies) does not always imply recovery of contractile function.

MYOCYTE NECROSIS

That ischemia–reperfusion injury causes myocardial necrosis of myocytes is well known. Necrosis is defined as “accidental” cell death involving a failure to generate high-energy phosphate fuel in the form of ATP, cell swelling secondary to impaired function of the ionic pumps of the cell and consequent gain in intracellular water, intracellular accumulation of calcium, and a terminal disintegration of the cell membrane with release of cell contents into the pericellular region. The latter event provides a leukotactic signal that precipitates an inflammatory response by neutrophils and macrophages, which are in turn recruited to the site of injury to “mop up” cell debris. These neutrophils and macrophages are programmed to attack myocytes that have been “marked” for destruction by the expression of certain adhesion molecules on myocytes, which act as ligands allowing attachment of the inflammatory cells. Myocytes express certain adhesion molecules, such as intracellular adhesion molecule-1 (ICAM-1) and endothelial–leukocyte adhesion molecule-1 (ELAM-1), that allow neutrophils to attach by CD18-dependent mechanisms (Bullough *et al.*, 1996; Smith *et al.*, 1991; Youker *et al.*, 1992) and stimulate a burst of oxygen radicals which then damages or kills the myocyte (Entman *et al.*, 1992). The expression of adhesion molecules on the cell surface of myocytes is facilitated by exposure of the cells to circulating cytokines such as IL-6, TNF- α , and complement fragments. In addition, the release of chemokines such as macrophage inflammatory protein-2 (MIP-2) and monocyte chemotactic protein (MCP) (Massey *et al.*, 1995) directly stimulate the recruitment of leukocytes to sites of ischemia–reperfusion injury. Hence, neutrophil activation at the endothelial surface ultimately leads to the movement through the endothelium (endothelial transmigration) into the interstitial compartment, facilitated by chemotactic stimuli released by myocytes, where direct contact to

the myocytes leads to damage or cell death. However, sublethal damage or frank necrosis to myocytes does not depend wholly on direct contact with inflammatory cells. Cytokines and oxygen radicals released from neutrophils at the endothelium may lead to necrosis by directly affecting underlying myocytes or by inducing severe injury to the microvasculature, thereby precipitating a no-reflow state with subsequent secondary ischemia.

Nitric Oxide Therapy to Reduce Ischemia–Reperfusion Injury

Direct Scavenging of Superoxide Radicals by NO

Both NO and superoxide anions are radical species. Both species of radicals can react with biological tissues to generate products of oxidation. However, these reactive species can neutralize each other in a biradical reaction with a 1:1 stoichiometry that is essentially diffusion limited. The reaction proceeds at a rate of $6.7 \times 10^9 M^{-1} s^{-1}$, which exceeds the reaction rate between superoxide anions and superoxide dismutase by a factor of approximately three. In fact, the reaction of NO with superoxide radicals outcompetes the endogenous superoxide dismutases present in the tissue. In addition, the reaction is essentially irreversible due to its highly exothermic nature, with the release of 22 kcal/M. Because of the equimolar stoichiometry of the reaction, either substrate can be rate limiting, depending on its availability, but conversely an increase in one substrate can overwhelm and quench the physiological effects of the other (Rubanyi and Vanhoutte, 1986). Hence, either superoxide radical or NO is a factor in determining the *in vivo* concentration and physiological actions of the other radical species. Under normal conditions, the production of superoxide radicals is limited, although NO is produced tonically at relatively higher (low nanomolar) concentrations (Kelm and Schrader, 1990). However, the production of both superoxide and NO is greatest during early reperfusion following a period of ischemia, and both molecules are placed within the same proximity in and adjacent to the vascular wall, making their interaction and conneutralization likely. On the one hand, this biradical neutralization reaction reduces the concentration of a potentially harmful oxidant derived from several sources, including activated neutrophils and activated endothelium. On the other hand, this reaction reduces the biological availability of NO and attenuates its physiological effects (Gryglewski *et al.*, 1986; Rubanyi *et al.*, 1989). The administration of superoxide dismutase to vascular ring preparations stimulated by inflammatory mediators will produce increased tonic vasodilator tone as a result of increased availability of NO. Peroxynitrite ($ONOO^-$, the major reaction product of this biradical reaction between NO and superoxide radicals, has potent oxidant actions and is more stable than either of its two reactants. The important physiological effects of $ONOO^-$ impacting on salvage or injury induced to the vascular wall and the myocardium will be discussed later.

Effects of NO on the Coronary Vascular Endothelium

The ability of nitric oxide to affect multiple points (neutrophil activation, endothelial activation) in the neutrophil–endothelial cell adhesion process makes it a potent therapeutic agent in the treatment of the inflammatory component of ischemia–reperfusion injury leading to necrosis and contractile dysfunction. At nanomolar concentrations that do not produce vasodilation, NO attenuates the expression of certain key adhesion molecules, notably E-selectin and ICAM-1 on the endothelium and CD11/CD18 on the neutrophil (DeCaterina *et al.*, 1995; Ohashi *et al.*, 1997). In addition, NO inhibits superoxide anion production from the endothelium by direct action in the NADPH oxidase system (Clancy *et al.*, 1992). By acting on the expression of adhesion molecules on endothelial cells and neutrophils, NO inhibits the proximal steps in the pathogenesis of postischemic injury, thereby truncating subsequent pathways distal to the point of interdiction.

As discussed earlier, the expression of selectin (P-selectin) and members of the immunoglobulin superfamily [ICAM-1, vascular cell adhesion molecule (VCAM-1)] is increased after ischemia (Weyrich *et al.*, 1995), which has been associated with increased adhesion of neutrophils to the endothelium, an impaired release of NO by the vascular endothelium, and increased tissue damage after myocardial (Sluiter *et al.*, 1993; Weyrich *et al.*, 1993) or intestinal (Carden *et al.*, 1993) ischemia–reperfusion and other inflammatory-type conditions (Foreman *et al.*, 1994). Kubes *et al.* (1991) reported that inhibition of NO synthase activity with L-NAME increased PMN adherence to feline mesenteric postcapillary venules, measured by intravital microscopy, suggesting that endogenous NO modulates neutrophil–endothelial cell interactions. Because P-selectin is upregulated during reperfusion in association with a decrease in NO production by the endothelium, a regulatory connection between NO and the mechanism of P-selectin surface expression on the vascular endothelium was suggested.

In the heart, Weyrich *et al.* (1993) showed that P-selectin was increased within minutes after the onset of reperfusion, and that immunoneutralization of this adhesion molecule with a monoclonal antibody attenuated postischemic injury. A subsequent study by Davenpeck *et al.* (1994b) demonstrated that superfusion of the feline mesenteric microcirculation with L-NAME attenuated NO generation and increased PMN adherence to the venular endothelial surface in conjunction with an increased surface expression of P-selectin. These physiological responses were reversed by the coadministration of L-arginine and a cGMP analog (8-bromo-cGMP), thereby implicating NO as the active molecule. Importantly, NO inhibits the surface expression of these key adhesion molecules. Conversely, blockade of NO production with L-NAME or other NO synthase inhibitors increases the surface expression of these adhesion molecules. Hence, NO may be involved in regulating the expression of adhesion molecules and the subsequent reduction in adhesion molecule-dependent tissue injury in response to

ischemia–reperfusion. The loss of NO generation secondary to reperfusion injury may be a major factor governing the increased surface expression of adhesion molecules on endothelium and neutrophils at this time.

The mechanism of adhesion molecule downregulation by NO has been investigated. Armstead *et al.* (1997) demonstrated that NO donor agents or L-arginine attenuated the expression of P-selectin protein and mRNA in cultured human iliac artery and vein endothelial cells. Conversely, the NOS inhibitor L-NAME increased the expression of P-selectin on these endothelial cells. Furthermore, DeCaterina *et al.* (1995) reported that NO donors downregulated the expression of VCAM protein on endothelium as well as mRNA for both ICAM-1 and VCAM. Attenuation of the transcription and translation of these adhesion molecules was linked to a decrease in TNF- α -stimulated activation of NF- κ B, a transcription factor that promotes or signals the synthesis of adhesion molecules by turning on the target gene after translocation of the nuclear factor from the cytosol to the nucleus. This same decrease in NF- κ B activity was not present in endothelium exposed to cGMP, glutathione, or nitrite (DeCaterina *et al.*, 1995), implying a direct action by NO. In summary, these data suggest that NO attenuates not only the surface expression of these adhesion molecules, but also the signaling processes involved in the transcription and translation of new adhesion molecule proteins. This important action of NO has the potential to decrease the adherence of neutrophils to endothelium and their ultimate accumulation in the myocardium following ischemia and reperfusion in the early phases (minutes) as well as over the longer term requiring *de novo* synthesis.

Therapy to Increase Endogenous Nitric Oxide

Endogenous NO participates in the tonic modulation of various postischemic physiological processes including electrophysiological abnormalities and myocardial injury (i.e., infarction). In view of the important modulation of postischemic injury by NO, tonically released NO may provide endogenous cardioprotection.

In vivo, Pabla and Curtis (1996) reported that the reduction of endogenous NO generation by L-NAME in isolated perfused rabbit hearts increased the incidence of reperfusion-induced ventricular fibrillation, which was reversible by coinfusion with L-arginine, thereby ascribing a beneficial electrophysiological effect to NO. Furthermore, the study by Williams *et al.* (1995) using an *in vivo* rabbit model demonstrated that the systemic administration of the eNOS inhibitor L-NA either before ischemia or just prior to reperfusion increased infarct size ($51 \pm 2\%$ and $49 \pm 3\%$ of area at risk, respectively, compared to $27 \pm 2\%$ of area at risk in control). In agreement with the study of Williams *et al.* (1995), other studies have reported a reduction in the time to ischemic contracture in globally ischemic hearts (Pabla and Curtis, 1996), a decrease in postischemic contractile recovery (Pabla *et al.*, 1996), and an increase in infarct size (Hoshida *et al.*, 1995) with NOS inhibition, suggestive of

withdrawal of NO-mediated cardioprotection. Reductions in contractile recovery and infarct size were associated with a concomitant increase in neutrophil accumulation. These effects on arrhythmias, contractile dysfunction, and infarction were reversed by coinfusion of L-arginine. These data suggest a cardioprotective role for tonically released NO that, when NO is withdrawn, exacerbates postischemic injury.

In contrast to these reports of beneficial effects of endogenous NO, a number of studies have shown that NO actually increases postischemic arrhythmias, contractile dysfunction, and infarction. This notion that NO increases postischemic injury, by extension, would suggest that blockade of NOS activity would reduce postischemic damage. Accordingly, Woolfson *et al.* (1995a) reported that the L-arginine analog L-NAME reduced infarct size in an *in situ* rabbit model, which seemed to support a deleterious role for NO. In addition, Schultz and Wambolt (1995) demonstrated that the cardioprotective effects resulting from NOS inhibition with L-NAME was abolished by coadministration of L-arginine but not by D-arginine. In contrast, Sun and Wainwright (1997) reported that neither the NOS inhibitor L-NAME nor the NO donor agent C87-3754 altered the incidence and severity of ventricular arrhythmias during a 30-min period of coronary artery occlusion in anesthetized rats. Hence, these data would suggest that endogenous NO is deleterious in myocardial ischemia–reperfusion.

The discrepancy between the reported beneficial effects versus the deleterious effects of endogenous NO on postischemic arrhythmias and infarct size is not fully resolved, but it may involve several factors. The differences in observed effects may be due, in part, to the choice of L-arginine analog. Methylated analogs demonstrate muscarinic-like antagonistic effects not observed with nonmethylated analogs. In addition, L-NAME and other NO synthase inhibitors may induce severe vasoconstriction and ischemia when administered in high concentrations, so that more severe ischemia occurs with these inhibitors, or vasoconstriction prevents full reperfusion and a persistent ischemia which would increase the degree of injury. The reduction in postischemic damage reported with NOS inhibition may be due to a compensatory release of the cardioprotective autacoid adenosine due to myocardial ischemia (Patel *et al.*, 1993a; Woolfson *et al.*, 1995b). In the study by Patel *et al.* (1993b), ischemia induced by NOS inhibition (and presumably to reduced NO release) is supported by an increase in lactate release (Patel *et al.*, 1993b). Therefore, the cardioprotection may have been related to the effects of adenosine (Patel *et al.*, 1993b) released by ischemic myocardium rather than to the reduced NO levels (which were not measured in this study).

Endogenous NO can be therapeutically augmented by administering the precursor for NO, L-arginine. Although L-arginine appears in the blood in sufficient concentrations to saturate NO synthase, supplemental L-arginine has been reported to increase NO release (directly or indirectly measured) by the coronary vascular endothelium (Engelman *et al.*, 1995a; Guo *et al.*, 1996; Palmer *et al.*, 1988). In isolated rat aortic endothelial cells, 1 mM L-arginine increased NO

generation by approximately 40% above basal levels (Guo *et al.*, 1996). The nonmetabolized enantiomer D-arginine, at the same concentration, did not increase tonically released NO. Hence, the provision of L-arginine stimulates a concentration-dependent production of NO.

The cardioprotection from reperfusion injury observed with L-arginine may be derived from the potent antineutrophil effects of NO. L-Arginine was reported by Sato *et al.* (1996) to significantly inhibit neutrophil adherence to coronary artery endothelium when stimulated with platelet activating factor (PAF). PAF increased the adherence to endothelium fourfold, whereas 10 mM L-arginine attenuated this increased adherence to control levels (Fig. 9). L-NA reversed the inhibitory effects of L-arginine, whereas equimolar concentrations of D-arginine failed to reduce neutrophil adherence, both interventions indicating an NO-mediated mechanism of attenuated neutrophil adherence. Interestingly, L-arginine had no direct effect on neutrophil generation of superoxide radicals when stimulated by PAF, suggesting that the effects of L-arginine were on the adherence process, rather than other processes involved in the inflammatory-like responses (i.e., stimulation of P-selectin expression on endothelium). The concentration of L-arginine found to be effective in reducing neutrophil-mediated effects on the coronary vascular endothelium was between 3 and 10 mM (Nakanishi *et al.*, 1992; Sato *et al.*, 1995b; Weyrich *et al.*, 1992), whereas greater concentrations of L-arginine have been associated with myocardial or endothelial injury.

The above *in vitro* data suggested that L-arginine may be useful in limiting endothelial dysfunction and infarction secondary to ischemia–reperfusion *in vivo*. In models of regional ischemia, intravenous (Weyrich *et al.*, 1992) or intracoronary (Nakanishi *et al.*, 1992) supplementation with L-arginine at the time of reperfusion significantly decreased

both postischemic coronary artery endothelial dysfunction and infarct size. In a study by Weyrich *et al.* (1992), using a feline model of 90 min of LAD occlusion and 270 min of reperfusion, the intravenous infusion of L-arginine significantly reduced infarct size, which was associated with a decrease in neutrophil accumulation in the area at risk and with a reduction in endothelial function in the ischemic–reperfused coronary artery. In neither of the cited studies (Nakanishi *et al.*, 1992; Weyrich *et al.*, 1992) was there a significant hemodynamic effect (hypotension) of L-arginine infusion. In the study by Nakanishi *et al.* (1992), 10 mM L-arginine was infused in the LAD coronary artery at the onset of reperfusion. Infarct size in the L-arginine group was reduced from $35 \pm 2\%$ of the area at risk to $18 \pm 3\%$ (Fig. 10A), whereas infarct size was actually increased in a group receiving equimolar concentrations of D-arginine (infarct size $49 \pm 5\%$ of area at risk), confirming that the infarct-sparing effect of L-arginine likely occurred by the L-arginine–NO synthase pathway, without a significant metabolic or other effect of L-arginine unrelated to NO. Consistent with the antineutrophil effect of endogenously released NO, there was less neutrophil accumulation in the area at risk with L-arginine treatment at reperfusion than in vehicle or D-arginine treated groups (Fig. 10B). Neither postischemic regional contractile function nor postischemic myocardial blood flow was improved with L-arginine treatment in this study. However, postischemic endothelial vasorelaxation responses to acetylcholine were significantly better in the L-arginine-treated group compared to both the vehicle group and the D-arginine group (Fig. 10C). Hence, the cardioprotection observed with L-arginine is due to increased NO release and to an NO-related reduction in neutrophil-mediated injury.

The relatively small infarct-sparing effect of L-arginine reported in the study by Nakanishi *et al.* (1992) raised the question of whether maximal cardioprotection was achieved with the dose of intracoronary L-arginine used, or whether ischemia limited the ability of the endothelium to generate NO in the presence of enhanced concentrations of L-arginine. Damaged endothelium has a defect either in receptor signaling mechanisms of stimulating eNOS or in the activity of the enzyme system itself (Giraldez *et al.*, 1997). Hence, the responses to enhanced concentrations of L-arginine may likewise be limited, thereby reducing the concentration-dependent generation and release of NO. In addition, too high a concentration of L-arginine may be accompanied by increased neutrophil-mediated damage and tissue injury. Further investigation is needed on the association between dose of L-arginine used and the limitation imposed by endothelial injury on the extent of cardioprotection achieved by precursor therapy.

Figure 9 The effects of L-arginine on adherence of fluorescently labeled canine neutrophils to normal (control) or thrombin-stimulated coronary artery segments detected by epifluorescence microscopy. Stimulation with 2 U/ml of thrombin increased neutrophil (PMN) adherence fourfold over unstimulated coronary artery endothelium. L-Arginine (10-mM) decreased adherence to control levels, which was reversed by the nitric oxide synthase inhibitor L-NA. L-NA alone tended to increase neutrophil adherence above thrombin stimulation alone (PMN group) by inhibition of basal NO release.

Exogenous NO Therapy

The potential limitation of damaged coronary endothelium to generate cardioprotective quantities of NO may potentially be overcome by the exogenous administration of

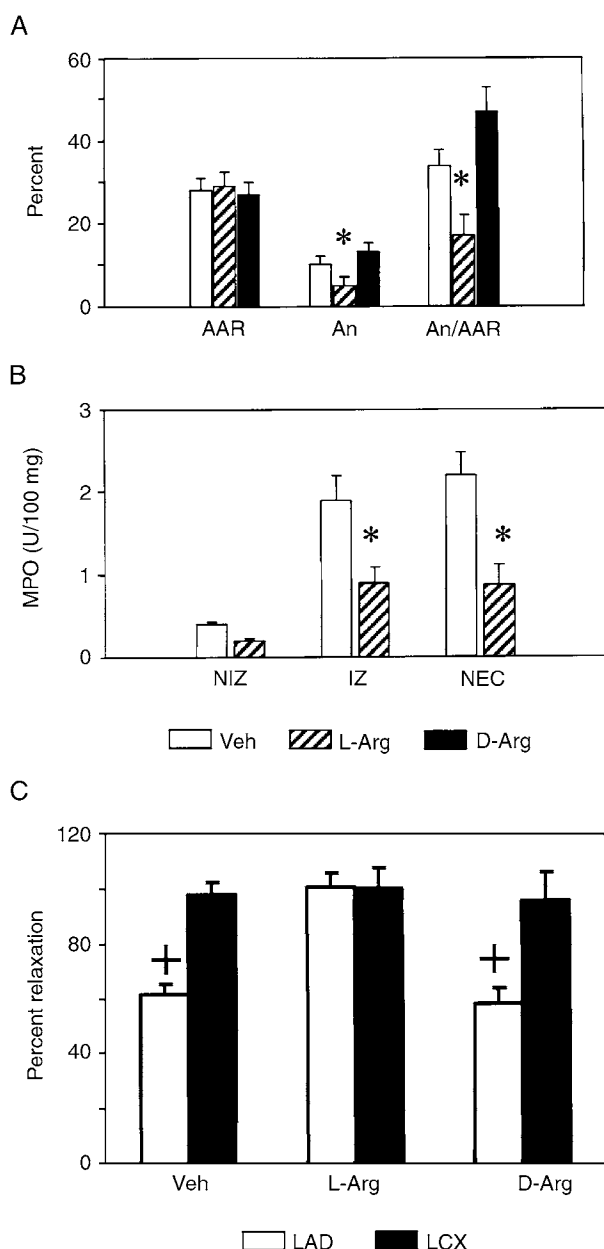

Figure 10 Intracoronary L-arginine during reperfusion on infarct size (A), neutrophil accumulation measured by tissue myeloperoxidase activity (B), and relaxation responses of ischemic–reperfused (60 min followed by 270 min, respectively) LAD coronary artery to acetylcholine (C). Veh, vehicle-treated group; LCX, left circumflex coronary artery; +, $p < 0.05$ versus Lcx responses in A; *, $p < 0.05$ versus Veh in B and C. From Vinten-Johansen *et al.* (1999), with permission.

agents that donate NO *in vivo*. The exogenous approach to NO therapy using NO donors administered only at the onset of reperfusion was first reported by Johnson *et al.* (1990) in a feline model of regional myocardial ischemia–reperfusion (90-min LAD occlusion followed by 4.5 hours of reperfusion) using subvasodilator concentrations of intravenous acidified (pH 7.2) NaNO₂ (12.5–50 mM/kg/hour) as an NO donor agent or authentic nitric oxide gas dissolved in saline to achieve local concentrations approximating 2–10 nM

(Johnson *et al.*, 1991). Both forms of NO therapy decreased infarct size by approximately 75%, concomitant with a similar reduction in plasma creatine kinase activity. The reduced infarct size was associated with decreased neutrophil accumulation in the area at risk measured by tissue myeloperoxidase activity. These data suggest that NO therapy introduced at the time of reperfusion reduced myocardial infarction through an antineutrophil mechanism. Subsequent studies have demonstrated similar cardioprotective effects of various classes of organic nitrates that release NO readily (D. J. Lefer *et al.*, 1993b; Pabla *et al.*, 1996; Siegfried *et al.*, 1992a) and of nitrosylated molecules (Delyani *et al.*, 1996) in models of *in vivo* coronary occlusion and reperfusion. The organic NO donor agents include the sydnonimines, the cysteine-containing donors, and the nonoates. The organic donors release NO either spontaneously or after bioconversion of the parent molecule. Nitroglycerin is the classic prototype NO donor agent, but it is a poor NO donor because bioconversion is required by a cysteine-containing enzyme that is partially depleted in the microvasculature after ischemia–reperfusion. In addition, tolerance to the classic nitrates develops with prolonged exposure to the agent. Other organic NO donor agents, such as the early prototype sydnonimines [e.g., 1,3-morpholina-sydnonimine hydrochloride (SIN-1)], release superoxide concomitantly with NO, thereby providing the substrates and the close proximity required to generate ONOO[−] via a biradical reaction.

A cysteine-containing organic donor compound, SPM-5185 [(*N*-(3-hydroxy-pivaloyl)-*S*-(*N*'-acetylalanoyl)-L-cysteine ethyl ester) (Schwarz Pharma, Monheim, Germany), readily releases NO spontaneously (D. J. Lefer *et al.*, 1993b,c). This NO donor agent was tested in a canine model of LAD occlusion and reperfusion in which infarct size, neutrophil accumulation, and postischemic endothelial function in ischemic–reperfused and nonischemic coronary arteries were measured. SPM-5185 was administered by intracoronary infusion (500 nM) during reperfusion after 1-hour LAD occlusion. SPM-5185 reduced infarct size from $47.5 \pm 9\%$ to $14.5 \pm 4\%$ of the area at risk, which was paralleled by a similar decrease in plasma creatine kinase activity. In addition, the infarct reduction was associated with a 58% reduction in neutrophil accumulation (tissue myeloperoxidase activity) in the area at risk (D. J. Lefer *et al.*, 1993c). The nonactive form of the compound, SPM-5267, had no effect on any of the physiological end points measured. Similar cardioprotection has been achieved with other NO donor agents introduced by intracoronary infusion at the onset of reperfusion (Pabla *et al.*, 1995).

In addition to the intracoronary route of delivery, the intravenous route has also been shown to be effective. Siegfried *et al.* (1992a,b) administered SPM-5185 (Siegfried *et al.*, 1992b) or the other organic donor agents SIN-1 and C87-3754 (Siegfried *et al.*, 1992a) intravenously in a feline model of LAD occlusion and reperfusion with similar degrees of infarct reduction and attenuation of postischemic endothelial dysfunction in the occluded–reperfused LAD coronary artery. In contrast to L-arginine, these NO donor agents have

been reported to directly attenuate superoxide radical production (measured by cytochrome *c* reduction) and attenuate adherence of neutrophils to coronary artery endothelium.

Whether the cardioprotection afforded by NO therapy is predominantly due to inhibition of neutrophil-mediated damage was studied by Pabla *et al.* (1996). These investigators used the isolated perfused rat heart model in which the heart was perfused in the presence or absence of human neutrophils for a short period during the early moments of reperfusion. These investigators did not show any significant improvement in postischemic contractile function (left ventricular developed pressure) with NO donor agents in hearts perfused without neutrophils, but some reduction was observed in perfusate creatine kinase activity. However, a greater reduction in creatine kinase activity was seen in the hearts perfused with neutrophil-supplemented buffer in which NO donor agents were added. Therefore, NO seems to inhibit neutrophil-mediated injury leading to infarction and endothelial dysfunction, but it may not prevent contractile dysfunction.

To summarize, NO exerts potent antineutrophil effects by attenuating superoxide radical generation and by inhibiting adherence to coronary vascular endothelium. In addition, NO attenuates the expression of adhesion molecules on the surface of the endothelium. These effects inhibit the inflammatory interaction between neutrophils and coronary endothelial cells. Accordingly, NO attenuates the distal consequences of ischemic–reperfusion injury (infarction, endothelial dysfunction, microvascular blood flow defects) in association with reduction in the accumulation of neutrophils in the myocardial area at risk.

Ischemia–Reperfusion Injury, the Vascular Endothelium, and Nitric Oxide in Cardiac Surgery

Cardiac Surgery as a Unique Model of Ischemia and Reperfusion

Cardiac surgery is a unique model of ischemia–reperfusion injury, and it has significant differences from its nonsurgical counterpart that impact on the application of NO-related therapy. Although cardiac surgery shares a common denominator of the cellular mechanisms of the postischemic inflammatory cascade and key mediators of parenchymal and endothelial cell injury with its nonsurgical counterpart (i.e., oxygen radicals, neutrophils), the frequency of ischemia and reperfusion events as well as the biological environment (bypass tubing, oxygenators, use of cardioplegic solutions, etc.) encountered in the surgical setting have an important impact on the pathophysiological processes leading to injury once the target vessel is reperfused. In conventional cardiac surgery, the patient is placed on the cardiopulmonary bypass (heart–lung machine), which consists of an oxygenator that exchanges oxygen and carbon dioxide with venous blood, with the arterialized blood being returned to the arterial system of the patient (Fig. 11). After cardiopulmonary bypass

Figure 11 Schematic diagram of cardiopulmonary bypass circuitry. From Casthely P. A. (1991). The anatomy of cardiopulmonary bypass. In "Cardiopulmonary Bypass: Physiology, Related Complications and Pharmacology" (P. A. Casthely and D. Bregman, eds.), pp. 23–35. Futura Publ., Mount Kisco, New York.

is initiated, and the heart and lungs are essentially "out of the loop" in maintaining the circulation; the myocardium is perfused by blood from the arterial system. During cardiac surgery, the aorta is cross-clamped, thereby separating the heart from the circulating blood and rendering the heart ischemic, and a chemical cardioplegia (cardio = heart, plegia = paralyzed, immobile) solution is delivered selectively to the heart to initiate elective cardiac arrest. This quiescent heart not only provides the surgical team with a bloodless field and quiet heart in which surgical precision is facilitated, but it also protects the heart from intraoperative ischemic injury by cooling the heart and delivering various cardioprotective agents (Buckberg, 1987, 1995; Vinten-Johansen and Cordell, 1992; Vinten-Johansen and Hammon, 1993).

Cardiopulmonary bypass is not innocuous, however, because the blood and the patient are exposed to surfaces (i.e., plastic tubing, plastic oxygenator) that are foreign in biological terms. These foreign surfaces are recognized as such by the immune system, which responds accordingly with an inflammatory response characterized by release of complement fragments C3a and C5a and of cytokines such as IL-6

and $\text{TNF-}\alpha$. These inflammatory mediators in turn mobilize a systemic inflammatory response in which neutrophils are activated, generate superoxide radicals and other cytokines, and adhere to vascular endothelium; the response is amplified by the recruitment of other inflammatory cells to sites of endothelial activation. This systemic response to cardiopulmonary bypass is similar to the inflammatory-like response engaged in ischemic–reperfusion injury, and it may, in fact, synergize with the inflammatory processes initiated by myocardial ischemia–reperfusion. Cardiopulmonary bypass, independent of myocardial ischemia, activates the complement cascade (Chenoweth *et al.*, 1981; Videm *et al.*, 1990) with the subsequent activation of neutrophils (Faymonville *et al.*, 1991) and their adherence-triggered release of cytotoxic products, all of which directly or indirectly (through recruitment of inflammatory cells) contribute to tissue injury in the ischemic–reperfused myocardium (Faymonville *et al.*, 1991; Lucchesi and Mullane, 1986). Therefore, the extracorporeal techniques used in cardiac surgery may themselves amplify the inflammatory responses initiated by myocardial (and other organ) ischemia–reperfusion injury, and thereby augment the total degree of injury (Boyle *et al.*, 1997). However, the cardioprotective techniques used in cardiac surgery, particularly cardioplegia solutions and their various additives, as well as hypothermia, reduce other pathological components of ischemic–reperfusion injury, potentially attenuating postsurgical injury.

Cardioplegia solutions are either of an acellular (crystalloid) or blood-based formulation, and they are delivered only to the heart after cardiopulmonary bypass is initiated. A cross-clamp placed on the aorta effectively separates the heart from the rest of the circulation, allowing delivery of the cardioplegia solution selectively to the heart. The solution is designed to (1) arrest the heart using high potassium concentrations (~ 20 mEq/liter) or hyperpolarizing agents (Cohen *et al.*, 1993; de Jong *et al.*, 1990) in order to present the surgeon with a motionless heart and thereby facilitate surgical precision and reduce energy demands, (2) cool the heart to various levels of hypothermia in order to further reduce energy demands and hence protect the heart during periods when the heart is not receiving a nutritional supply of blood or cardioplegia, (3) provide a vehicle for the delivery of various drugs to reduce ischemic injury and metabolically resuscitate the heart, and (4) act as a buffer before the heart is reperfused with normal systemic blood (modified reperfusate) in order to reduce reperfusion injury.

To summarize, the differences between the nonsurgical model and the surgical model of ischemia–reperfusion include the following: (1) multiple encounters with both ischemia and reperfusion, which add a dimension of complexity that is absent from nonsurgical models; (2) the accentuated roles of neutrophils and of the inflammatory mediators such as complement, tumor necrosis factors ($\text{TNF-}\alpha$), and interleukins that are activated secondary to extracorporeal equipment (plastic tubing, cardiectomy reservoirs, oxygenators, suckers, etc.) used in “on-pump” heart surgery, which amplify the inflammatory response involving these compo-

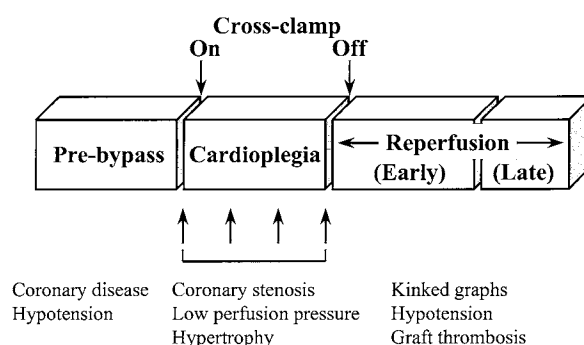

Figure 12 Points where potential ischemic injury can occur during a routine cardiac operation. The three “windows” of potential injury are (1) before bypass, (2) during the delivery of intermittent cardioplegia, and (3) after initiation of reperfusion by removal of the aortic cross-clamp. The arrows indicate the delivery of blood cardioplegia.

nents; and (3) surgery-specific techniques such as hypothermia and cardioplegia that alter the mechanisms of both ischemia and reperfusion in complex and sometimes unpredictable ways.

During cardiac surgery, ischemic injury to the myocardium can be encountered at three major time points, as summarized in Fig. 12: (1) pre-bypass ischemia that is encountered prior to the initiation of cardiopulmonary bypass or the delivery of cardioplegia solution (i.e., “unprotected” ischemia), and is related to attenuated perfusion to the myocardium secondary to coronary artery occlusions or extreme hypotension; (2) “protected” ischemia that occurs during the cardiac surgery using chemical cardioplegia delivered intermittently for several minutes followed by a period of no cardioplegia delivery; and (3) ischemia after the heart is reperfused, when closure of the coronary artery grafts or extreme hypotension limits blood flow to the heart. Reperfusion injury can be encountered (a) after resuscitation from prebypass hypotension or arrest, (b) during the infusions of cardioplegia (perfusion injury) dependent on the composition and delivery pressure of the cardioplegia solution, and (c) after removal of the aortic cross-clamp when the myocardium is perfused by native unmodified blood. Reperfusion injury can occur acutely (<4 hours after reperfusion) and during later phases of reperfusion during the first 4 to 6 hours after removal of the aortic cross-clamp. Oxygen radicals and neutrophil–endothelial cell interactions feature prominently in the acute phase of reperfusion injury (Dreyer *et al.*, 1991a,b; Zhao *et al.*, 1998; Boyle *et al.*, 1996).

Endothelial Injury in Cardiac Surgery

Patients undergoing cardiac surgery for valve repair or replacement, correction of anomalies of the great vessels, coronary artery bypass grafting, etc., often have underlying diseases such as hyperlipidemia, hypertension, and atherosclerosis. Endothelial dysfunction plays a major role in the pathological profile of these medical conditions in that the generation of NO has been attenuated as a result of the pri-

mary or secondary disease, or it is a part of the pathogenesis of the disease. This preoperative endothelial dysfunction has an impact on the postoperative outcome and management of the patient. Acute spasm of arterial grafts, acute loss of patency of any biological vascular conduit, and long-term patency are all factors that may be influenced by the preoperative health of the endothelium and its responses to cardiopulmonary bypass and/or surgical revascularization procedures. Loss of full graft patency or vascular coagulopathies may precipitate acute cardiac failure or other acute or long-term complications. The health of the endothelium also governs to some extent the degree of reperfusion injury that occurs as a consequence of surgical revascularization. Therefore, strategies to mitigate vascular dysfunction and protect the heart and other organs can use the concepts of nitric oxide to improve postoperative outcome over a broad range of disease presentations.

In the previous section on nonsurgical ischemia–reperfusion injury, the effects of ischemia and subsequent reperfusion on endothelial function and other end points were discussed. In cardiac surgery, however, intraoperative ischemia may superimpose on preoperative ischemia and any contributing endothelial dysfunction. In addition, hypothermia and cardioplegia solutions of various formulations and modalities of delivery may alter the response of the heart to ischemia and reperfusion. Figure 13 shows coronary artery endothelial function assayed as vasodilator responses to acetylcholine after 45 min of global normothermic ischemia, with or without reperfusion, or after multidose, hypothermic potassium blood cardioplegia for an additional hour of “protected” ischemia with or without reperfusion (Nakanishi *et al.*, 1994). Note from Fig. 13 that endothelial-dependent responses to acetylcholine were normal after the 45-min period of ischemia without reperfusion, but that dysfunction was expressed after reperfusion. Interestingly, the additional hour

of hypothermic cardioplegia was not associated with a decrease in endothelial responses to acetylcholine, despite the intermittent nature of delivery, likely due to the protective attributes of the cardioplegia solution (hypothermia to 10°C myocardial temperature, buffering of acidosis, metabolic substrates in blood, increased oncotic properties). However, when the hearts were reperfused with normal systemic blood by removing the aortic cross-clamp, endothelial responses showed significant dysfunctional vasorelaxation responses to acetylcholine. A similar response profile was observed for the endothelial receptor-independent agent A23187, suggesting that there was a defect in the NO synthase activity. Smooth muscle relaxation responses to the NO donor agent acidified (pH 2.0) NaNO₂ were comparable to the control group, indicating normal function of the vascular smooth muscle. Endothelial dysfunction after global ischemia–reperfusion was also associated with morphological abnormalities in endothelial structure, including partial or complete detachment of endothelial cells from the basement membrane, hypervacuolation of endothelial cells present, and neutrophil attachments. These data suggested that the period of cardioplegic arrest with blood cardioplegia solution did not cause additional endothelial dysfunction despite the hour of cold arrest, but that endothelial dysfunction occurred during reperfusion with normal blood, similar to that observed with normothermic ischemia (without cardioplegia) followed by reperfusion. This observation is consistent with endothelial dysfunction observed with regional ischemia discussed earlier. Hence, strategies are necessary to address this postcardioplegia reperfusion injury.

Cardioprotective Effects of Nitric Oxide in Cardiac Surgery

As in the use of NO-related therapy in the treatment of myocardial ischemia–reperfusion injury, strategies for delivering NO therapy fall into two broad categories: (1) modulation of endogenous NO by addition of NO precursors or agents that stimulate native NO production by NO synthase and (2) administration of authentic NO or NO donor agents. These therapeutics may be applied systemically (appropriate for pre-bypass or off-pump applications) or as an adjunct to the cardioplegia solution, whereby higher concentrations of the agents can be achieved than are tolerated systemically.

ENHANCING ENDOGENOUS NITRIC OXIDE RELEASE

Increasing endogenous NO can be achieved by supplementing the cardioplegia solution with its precursor L-arginine. The ideal effect of this therapy is to enhance recovery of both the endothelium and the myocyte, the latter in terms of contractile function as well as viability. In surgical models using antecedent ischemia (regional or global) with subsequent delivery of blood cardioplegia and reperfusion, blood cardioplegia supplemented with L-arginine demonstrated significant benefit over unsupplemented blood cardioplegia, consistent with the potent anti-inflammatory effects

Figure 13 Defects in endothelial-specific vasorelaxation responses to acetylcholine after 30 minutes of normothermic global ischemia, after global ischemia plus reperfusion, after global ischemia followed by 60 min cardioplegic arrest with multidose hypothermic blood cardioplegia, and after global ischemia and blood cardioplegia followed by normal blood reperfusion.

of NO. In a canine model of 90-min left anterior descending coronary artery ligation followed by cardioplegic arrest using blood cardioplegia, Sato *et al.* (1995a) reported that in the group in which blood cardioplegia was supplemented with 10 mM L-arginine (with a simultaneous intravenous infusion of 4 mg/kg/min starting at release of the cross-clamp), there was a 33% increase in postischemic systolic contractile function in the ischemic–reperfused area, a significant increase in regional compliance, and a 30% reduction in infarct size, compared to the group without L-arginine-supplemented blood cardioplegia. These beneficial effects of L-arginine-enhanced blood cardioplegia were associated with a significant decrease in neutrophil accumulation in the reperfused region compared to the unsupplemented group. In addition, coronary arteries taken from the ischemic–reperfused segment demonstrated better endothelial function compared to the unsupplemented blood cardioplegia group (Fig. 14). The beneficial effects of L-arginine were reversed by the NO synthase inhibitor L-NA administered intravenously before delivery of L-arginine-enhanced blood cardioplegia.

In a model of 20-min global normothermic ischemia, arrest with blood cardioplegia, followed by reperfusion, Mizuno *et al.* (1997) reported no postcardioplegia systolic or diastolic dysfunction, but they did not observe significant coronary artery endothelial dysfunction. This endothelial dysfunction was reversed by 2 mM L-arginine used as additive to the blood cardioplegia solution. The improved endo-

thelial function was associated with greater transcardiac nitrate/nitrite concentration in the cardioplegia affluent, suggesting that the adjunct L-arginine indeed increased the release of NO during delivery of the solution. These results have been corroborated by other studies in which cardioplegia solutions were supplemented with L-arginine (Engleman *et al.*, 1995b; Hiramatsu *et al.*, 1995a). Interestingly, 3 mM L-arginine given after the delivery of a crystalloid cardioplegia solution was reported by Engleman *et al.* (1996) to be detrimental. This observation may be related to the generation of the deleterious peroxynitrite by-product of the NO and superoxide neutralization reaction or to some unrecognized direct action of NO.

Other studies have reported cardioprotection by supplemental L-arginine in cardiac surgery models. Hiramatsu *et al.* (1995a,b) administered L-arginine during the early phase of reperfusion in a blood perfused isolated heart preparation; this protocol intentionally targeted reperfusion events mediated by neutrophils. This study demonstrated better recovery of postcardioplegia systolic function compared to unsupplemented cardioplegia. A similar benefit from L-arginine, administered at reperfusion, was also reported by Armani *et al.* (1995) in a cell-free perfusate system, suggesting that NO derived from L-arginine may exert beneficial effects independent of its antineutrophil effects, that is, quenching of superoxide anions. This is consistent with data reported by Pabla *et al.* (1996) showing a direct, but smaller, beneficial effect on recovery of contractile function independent of neutrophils compared to neutrophil-supplemented perfusate.

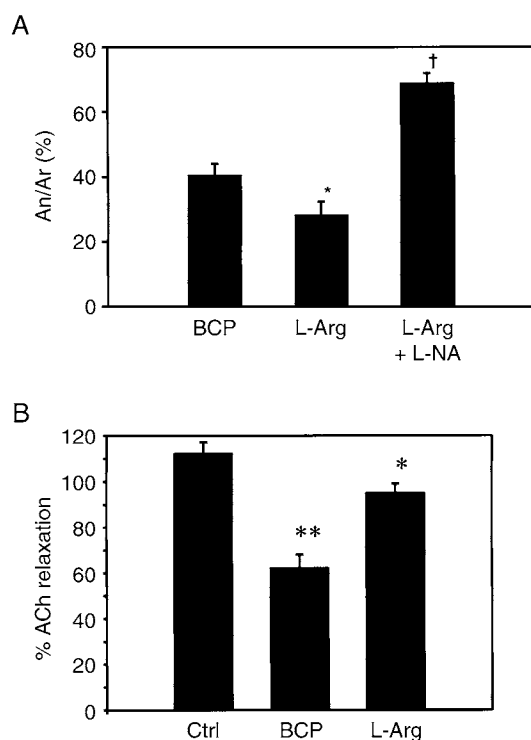

Figure 14 Effect of L-arginine-enhanced blood cardioplegia (BCP) on infarct size (A) and postischemic endothelial-specific coronary artery vasorelaxation responses to acetylcholine (B). Redrawn from Sato *et al.* (1995a).

EXOGENOUS DELIVERY OF NITRIC OXIDE DONORS

The studies of Nakanishi *et al.* (1992) and Sato *et al.* (1996) exposed several potential limitations in the therapeutic efficacy of the L-arginine-enhanced endogenous NO therapy in which the desired increased generation of NO from the coronary vascular endothelium is dependent on normal endothelial function. However, it has been demonstrated that ischemia and reperfusion impair NO generation by the endothelium (Sato *et al.*, 1997b). This potential limitation in the endogenous generation of nitric oxide may be overcome by administering nitric oxide donor agents. In a study by Nakanishi *et al.* (1995) using a canine model of cardiopulmonary bypass and cardioplegia, hearts were subjected to 30 min of normothermic ischemia to render the myocardium vulnerable to reperfusion injury. The ischemia was followed by 1-hour cardioplegia (4°C multidose blood cardioplegia, 4:1 blood:crystalloid ratio). Hearts received either unsupplemented blood cardioplegia (BCP) or blood cardioplegia supplemented with 10 μ mol/liter SPM-5185 (BCP + SPM). After an hour of cardioplegic arrest, the heart was weaned from cardiopulmonary bypass and reperfused for a total of 30 min off-pump. Postischemic left ventricular function, assessed by end-systolic pressure–volume relations (impedance catheter), was reduced by 53.7% of preischemic values in the unsupplemented blood cardioplegia group (Fig. 15A). In contrast, there was nearly complete postischemic functional recovery in the high-dose SPM-enhanced blood

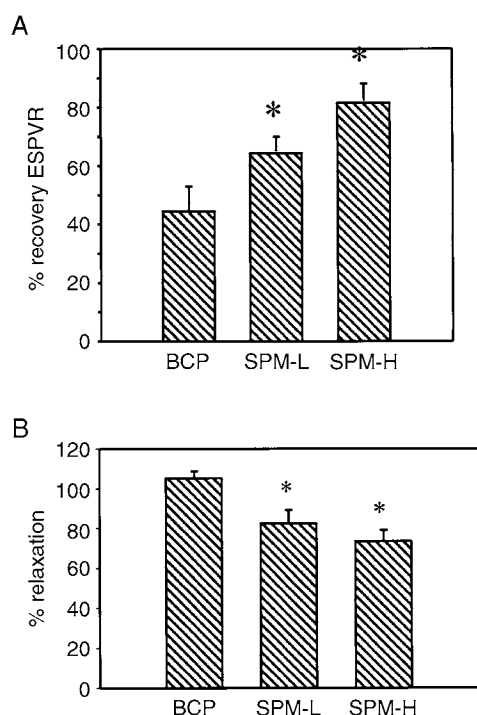

Figure 15 Cardioprotective effects of the NO donor agent SPM-5185 in blood cardioplegia on recovery of left ventricular function assessed by the end-systolic pressure–volume relationship as a percentage of baseline slope of the linear relationship (A) and on the maximum vasorelaxation responses of postischemic coronary arteries derived from incremental concentrations of acetylcholine (B). * $p < 0.05$ vs BCP.

cardioplegia group, with intermediate results in the 1 $\mu\text{mol/liter}$ SPM-5185 group. This improved functional recovery in the SPM-5185 blood cardioplegia group was associated with significantly reduced myeloperoxidase (MPO) activity (1.27 ± 0.45 U/100 mg tissue) in postischemic myocardium (used as an index of neutrophil accumulation), in contrast to the greater MPO activity in the unsupplemented blood cardioplegia group (3.36 ± 0.58 U/100 mg tissue). In postischemic coronary arteries isolated from these hearts, endothelium-dependent maximal relaxation responses to acetylcholine was attenuated by 27% in the unsupplemented blood cardioplegia group. However, endothelial responses recovered to approximately 100% in the high-dose SPM enhanced blood cardioplegia group (Fig. 15B). Therefore, this study demonstrated that addition of an NO donor agent in blood cardioplegia improved postischemic ventricular performance and postcardioplegia endothelial function in ischemically injured hearts, possibly by attenuating neutrophil-mediated damage. These data are consistent with findings in regionally ischemic–reperfused models in which NO donor agents were administered before the onset of reperfusion.

NO Effects on Mechanical Function of the Heart Relevant to Heart Surgery

Nitric oxide has been suggested to have inhibitory effects on cardiac systolic function, while increasing diastolic me-

chanics and thereby improving diastolic function. However, there is controversy over the effects of NO on the inotropic state and contractile function of the heart. Finkel *et al.* (1992) first reported a negative inotropic effect of cytokines (TNF- α) in papillary muscle preparations, which they attributed to the effects of NO. This observation would have relevance to procedures using cardiopulmonary bypass, because cytokines (Kawamura *et al.*, 1993; Steinberg *et al.*, 1993) as well as complement (Chenoweth, 1983; Davies *et al.*, 1991; Kirklin *et al.*, 1983) are elevated during bypass by exposure of blood to foreign surfaces and the triggering of cytokine and complement fragment release by ischemia–reperfusion. In support of stimulated release of NO during bypass, transmyocardial NO levels as well as NOS activity have been observed to be elevated after release of the cross-clamp during cardiac surgery (Hattler *et al.*, 1994), a time when cardiac functional depression is often observed. However, other studies have reported no negative inotropic effects of physiological concentrations of NO (Hasebe *et al.*, 1993; Weyrich *et al.*, 1994). The disparate observations may be related to the amount of NO released, which may be higher (micromolar range) with cytokine stimulation (i.e., of iNOS) compared to either endogenously released NO (0.1–1 nM in coronary circulation) (Kelm and Schrader, 1990) or therapeutic concentrations of NO donor agents (approximately 500 nM). Higher concentrations of NO released by endotoxin stimulation may mediate cardiac depression during the later stages of septic shock. However, in surgically or non-surgically reperfused postischemic hearts, any direct negative inotropic actions of NO may be overridden by the net cardioprotective effects of NO secondary to a reduction of neutrophil- and oxidant-mediated injury, resulting in better postischemic function (Hiramatsu *et al.*, 1995a,c; D. J. Lefer *et al.*, 1993a; Nakanishi *et al.*, 1995; Sato *et al.*, 1995c).

Peroxynitrite: The Product of Interaction between NO and Superoxide Anions

Nitric oxide and superoxide anions undergo a spontaneous and very rapid biradical, reaction forming the peroxynitrite anion. Peroxynitrite (ONOO^-) is formed at the near diffusion-limited rate of 5×10^9 to 6.7×10^9 $M^{-1}s^{-1}$ (Koppenol, 1998; Ma *et al.*, 1997a), which is three times greater than the reaction between superoxide radical and superoxide dismutase. This suggests that accumulation of superoxide radical levels may preferentially neutralize NO, reducing its bioavailability and thereby attenuating its physiological and cardioprotective functions. The reaction between these two radical species is potentially good and bad; a potentially deleterious anion is eliminated, but at the same time a potentially beneficial and cardioprotective NO molecule is eliminated. ONOO^- is a strong oxidant capable of forming intermediates with hydroxyl-like actions that produce biological tissue damage by hydroxylating aromatic compounds. In addition, ONOO^- induces cellular injury by

causing lipid peroxidation (Radi *et al.*, 1991), by inducing DNA fragmentation similar to that produced by apoptosis (Lin *et al.*, 1997a,b), by modifying proteins and plasma lipids (Van Der Vliet *et al.*, 1994), by depleting important plasma antioxidants such as glutathione and cysteine, and by nitrating proteins leading to cellular and organ dysfunction (Lopez *et al.*, 1997; Ma *et al.*, 1997a). Because both NO and superoxide radicals are produced during the early moments of reperfusion, the formation of peroxynitrite may be greatly increased at this important time. Studies demonstrate that ONOO⁻ is indeed a potential mechanism causing cellular injury in pathological conditions such as ischemia–reperfusion, inflammation, hypercholesterolemia, and angiotensin-induced hypertension (Lopez *et al.*, 1997; Ma *et al.*, 1997a,b; Nossuli *et al.*, 1998; Radi *et al.*, 1991; Xia *et al.*, 1996; Yasmin *et al.*, 1997).

ONOO⁻ may play a pivotal role in surgical and nonsurgical ischemic reperfusion injury. On the one hand, the production of ONOO⁻ may cause tissue damage by the mechanisms enumerated above. On the other hand, the nitrosylated breakdown products of ONOO⁻ may not only prevent toxic buildup of the anion, but they would generate potentially cardioprotective nitrates such as nitrosogluthathione. These diametrically opposed actions and fates of ONOO⁻ may resolve the equally opposing data regarding the cardioprotection or injury produced by NO. Whether ONOO⁻ generates deleterious by-products or whether it generates nitrosylated intermediates with cardioprotective actions (or authentic NO itself) is dependent on the biological environment, specifically whether the anion is present in a crystalloid environment or a blood environment. This has particular relevance to cardiac surgery in which the formulation of cardioplegia used provides a blood or crystalloid environment. *In vitro* studies conducted in crystalloid solutions demonstrate increased myocardial contractile dysfunction, increased infarct size, and direct endothelial toxicity via lipid peroxidation and DNA injury (Ma *et al.*, 1997a). In contrast, studies of ONOO⁻ conducted in a blood environment have shown benefits similar to those described above with authentic NO or NO donor agents.

Nossuli *et al.* (1998) reported a >50% reduction of infarct size and significant reduction in postischemic coronary artery endothelial dysfunction (vasorelaxation responses to acetylcholine) compared to a vehicle group in a feline model of 90 min of LAD occlusion and 270 min of reperfusion when 2 μ M authentic peroxynitrite was infused during reperfusion. However, in a follow-up study, Nossuli *et al.* (1998) showed that higher concentrations (20 μ M) of peroxynitrite were associated with increased infarct size and greater postischemic endothelial dysfunction. The actions of peroxynitrite in these two different environments may depend on the concentration of the anion and also on the presence of thiol-containing molecules such as glutathione, albumin, and cysteine, all of which are normal constituents of blood and are absent from crystalloid buffer solutions. Reaction of these compounds with peroxynitrite converts them to nitrosothiols such as nitrosogluthathione, which have

been found to mimic the physiological actions of NO, particularly the inhibitory effects on neutrophil–endothelial cell interactions (D. J. Lefer *et al.*, 1997).

This dichotomy in the physiological actions of peroxynitrite may impact on the decision to use NO in crystalloid cardioplegia solutions. In fact, the deleterious actions of L-arginine in crystalloid cardioplegia reported by Engelman *et al.* (1995a) may be related in part to the toxic buildup of peroxynitrite. Whether NO is converted to ONOO⁻ with subsequent negative consequences has an important impact on the surgical strategies of cardioprotection, namely, whether crystalloid or blood cardioplegia is used with NO-related therapeutics. This question was addressed in a study reported by Ronson *et al.* (1998). In this study, canine hearts *in vivo* were placed on cardiopulmonary bypass and subjected to 30 min of normothermic ischemia, followed by 1 hour of arrest using multidose hypothermic cardioplegia of either a crystalloid formulation (Plegisol) or 4:1 blood crystalloid: cardioplegia representing a crystalloid environment or a blood environment, respectively. Each formulation was subdivided into two groups: one with no supplemental ONOO⁻ and the other with 5 μ M authentic peroxynitrite. After the cardioplegia period, the hearts were reperfused for 2 hours. Ronson *et al.* (1998) found that in the crystalloid cardioplegia “environment,” ONOO⁻ was associated with significant decreases in postcardioplegia functional recovery and increased neutrophil accumulation compared to its counterpart without peroxynitrite. Conversely, peroxynitrite in the blood cardioplegia group increased functional recovery and decreased neutrophil accumulation compared to the blood cardioplegia group without peroxynitrite. Immunohistochemistry for nitrotyrosine, the “footprint” of the actions of peroxynitrite in tissue, confirmed that peroxynitrite was delivered at the tissue level. The results from this study are consistent with the sensitivity of ONOO⁻ to detoxification agents, and they may have clinical implications for NO additives used in crystalloid cardioplegic solutions with respect to myocardial protection, in that appropriate adjunct detoxifying agents may be necessary to detoxify ONOO⁻ generated by NO. A follow-up study by Nakamura *et al.* (1999) showed that glutathione added to this crystalloid cardioplegia solution containing peroxynitrite attenuates the deleterious effects of the anion (Fig. 16). ONOO⁻ in crystalloid cardioplegia was associated with endothelial dysfunction, which was completely reversed with 500 mM glutathione. Analysis of the cardioplegia effluent suggested that the ONOO⁻ was being converted by glutathione to nitrosogluthathione, and was thereby being effectively detoxified.

Summary

Nitric oxide is a pluripotent radical molecule whose physiological actions impact multiple disease processes such as atherosclerosis, hypercholesterolemia, circulatory shock, and ischemia–reperfusion injury in the pulmonary, cardiovascular, and other organ systems. The efficacy of NO in

Figure 16 EC₅₀ values for vascular relaxation responses to incremental concentrations of acetylcholine (left panel), the calcium ionophore A23187 (center panel) and the smooth muscle relaxant sodium nitroprusside (right panel) in the group with 5 μ M ONOO[−]-containing crystalloid cardioplegia (CCP) and a group in which 500 mM glutathione (GSH) was added to ONOO[−]-containing crystalloid cardioplegia (CCP + GSH). Maximal endothelial relaxations to acetylcholine were greater, and the EC₅₀ lower, in the GSH-containing group. * $p < 0.05$ versus group without glutathione.

attenuating ischemia–reperfusion injury in the cardiology and cardiac surgery settings derives from its inhibitory actions at a critical proximal point in the inflammatory cascade involving adhesion molecule-mediated interaction between neutrophils and endothelial cells with downstream effects on clinically relevant end points. NO therapy has been shown to reduce the following: infarct size, neutrophil activation and superoxide anion generation, the surface expression of adhesion molecules on the endothelium, the adherence of neutrophils to endothelium and subsequent accumulation in the reperfused area at risk, postischemic endothelial dysfunction, microvascular defects, and in some cases contractile dysfunction. NO may directly neutralize superoxide radicals, thereby inhibiting oxidant-mediated injury, but with the potential price of generating peroxynitrite unless thiol-containing agents are available to “detoxify” the anion. The attenuation of adhesion molecule protein synthesis at the molecular level by interfering with NF- κ B gene signaling has implications for long-term effects as well as acute effects on ischemia–reperfusion injury. Therapeutic agents are available that target the critical events in ischemia–reperfusion injury at subvasodilator concentrations, which is important clinically for the avoidance of hypotension in patients with the potential for hemodynamic instability of cardiac and vascular origin.

THE ROLE OF NITRIC OXIDE (NO) IN ISCHEMIC PHYSIOPATHOLOGY HAS GENERATED CONSIDERABLE CONTROVERSY BECAUSE NO MAY POSITIVELY IMPACT THE OUTCOME OF ISCHEMIA AS A POWERFUL VASODILATOR AND INHIBITOR OF BOTH PLATELET AGGREGATION AND PLATELET AND LEUKOCYTE ADHESION. NO ALSO PROMOTES TISSUE INJURY BY GENERATION OF OXYGEN RADICALS. USING NEURONAL NOS (nNOS) AND ENDOTHELIAL NOS (eNOS) KNOCKOUT MICE, WE DOCUMENTED THE DUAL ROLE OF NO IN CEREBRAL INFARCTION. nNOS KNOCKOUTS DEVELOPED 38% SMALLER INFARCTS THAN WILD TYPE AFTER PERMANENT MIDDLE CEREBRAL ARTERY (MCA) OCCLUSION. INFARCTS WERE 69% SMALLER IN nNOS KNOCKOUTS SUBJECTED TO TRANSIENT FOCAL ISCHEMIA, WITH LESS BRAIN EDEMA. BASAL cGMP LEVELS WERE LOWER IN MUTANTS AND DID NOT ENHANCE DURING ISCHEMIA CONTRARY TO THE ROBUST INCREASE IN WILD-TYPE MICE. NEUROLOGICAL DEFICITS ALSO WERE LESS. ADMINISTERING NITRO-L-ARGININE ELIMINATED THE RESISTANCE OF nNOS KNOCKOUTS TO FOCAL ISCHEMIA, PRESUMABLY BY INHIBITION OF eNOS, AND ITS NEGATIVE IMPACT ON CEREBRAL BLOOD FLOW, WBC, AND PLATELET FUNCTION. IN LINE WITH THIS EVIDENCE, LARGER INFARCTS DEVELOPED IN eNOS KNOCKOUT MICE AFTER MCA OCCLUSION. eNOS MUTANTS DISPLAYED MORE PRONOUNCED RCBF REDUCTIONS AFTER MCA OCCLUSION AND EXHIBITED LOWER RCBFs AT REDUCED PERFUSION PRESSURES DURING CONTROLLED HEMORRHAGIC HYPOTENSION. DYNAMIC CT SCANNING DEMONSTRATED THAT THE HEMODYNAMIC PENUMBRA WAS SIGNIFICANTLY SMALLER AND CORE LARGER IN eNOS MUTANTS COMPARED TO WILD-TYPE MICE. UNLIKE THE nNOS MUTANT, L-NA DECREASED INFARCT SIZE IN THE eNOS MUTANT, POSSIBLY BY INHIBITING nNOS. DNA DAMAGE WAS ALSO LESS IN nNOS KNOCKOUT ANIMALS, AS INDICATED BY FEWER POLY(ADP)RIBOSE POSITIVE CELLS COMPARED TO THEIR LITTERMATE CONTROLS. NUMBERS OF APOPTOTIC CELLS WERE SIGNIFICANTLY LOWER IN nNOS MUTANTS, SUGGESTING THAT EXCESS AMOUNTS OF NO GENERATED BY nNOS DURING CEREBRAL ISCHEMIA CAUSES CELL DEATH BY APOPTOSIS AS WELL AS NECROSIS. STRATEGIES AIMED AT UPREGULATING VASCULAR NO SYNTHESIS AND/OR INHIBITING PARENCHYMAL NO GENERATION ARE PROMISING TREATMENTS IN ACUTE ISCHEMIC INJURY.

Introduction

The role of nitric oxide (NO) in ischemic pathophysiology has generated considerable controversy because NO positively impacts the outcome of ischemia (e.g., as a powerful vasodilator and inhibitor of platelet aggregation, platelet adhesion, and leukocyte adhesion) but also promotes tissue injury (by generating peroxynitrite, a major mediator of cytotoxicity) (Dalkara and Moskowitz, 1994, 1997; Table I). To add to the complexity, NO protects tissues by scavenging superoxide (Niu *et al.*, 1994). Similarly, NO has been shown in part to mediate *N*-methyl-D-aspartate (NMDA) toxicity, but, on the other hand, its cationic redox form blocks NMDA receptor activation (Dawson *et al.*, 1991, 1996; Lipton *et al.*, 1993; Ayata *et al.*, 1997). More interestingly, peroxynitrite in small amounts protects against myocardial ischemia–reperfusion injury (Nossuli *et al.*, 1998). Moreover, NO donor agents administered during reperfusion protected pancreas (Benz *et al.*, 1998), liver (Ohmori *et al.*, 1998), and hind limb (Johnson *et al.*, 1998), whereas nitric oxide synthase (NOS) inhibitors protected against mesenteric ischemia (Takada *et al.*, 1998; Cuzzocrea *et al.*, 1998).

Possibly as a result of these opposing actions of NO, studies using NOS inhibitors or NO donor agents have produced conflicting results. The predominant effect may depend on the protocol and tissue type. For instance, the beneficial effects of neuronal NOS (nNOS) inhibition may be masked by drug-induced decreases in ischemic blood flow due to endothelial NOS (eNOS) inhibition. In ischemic brain, where neurons generate NO, the problem is equally complex. L-Nitroarginine methyl ester (L-NAME) or L-*N*^G-nitroarginine administration increases or decreases tissue injury in models of ischemia following middle cerebral artery (MCA) occlusion (for review, see Dalkara and Moskowitz, 1994). We have documented the detrimental role of neuronal NO and the protective effect of endothelial-derived NO on the development of cerebral infarction using mutant mice

Table I Positive and Negative Impacts of NO on Cerebral Ischemia

Positive	Negative
Enhancement of rCBF ^a	Disruption of cellular metabolism
Inhibition of platelet aggregation	Inhibition of DNA synthesis
Inhibition of platelet and neutrophil adhesion	Triggering Haber–Weiss reaction by releasing intracellular iron
Scavenging superoxide	Peroxyntirite formation
Inhibition of NMDA ^b current (NO ⁺ only)	DNA damage
	Activation of PARP ^c
	Induction of apoptosis

^arCBF, regional cerebral blood flow.

^bNMDA, *N*-methyl-D-aspartate.

^cPARP, poly(ADP-ribose) polymerase.

Table II Effect of Nitro-L-arginine on Infarct Size 24 Hours after Permanent MCA Occlusion in the Wild-type (SV-129) and Mutant Mouse Lacking Expression of Neuronal or Endothelial Isoforms of NOS

Treatment	Infarct size ^a		
	Wild type	Mutants	
		nNOS (–)	eNOS (–)
Vehicle	L	S	VL
After nitro-L-arginine	nc	L ^b	L ^b

^aL, large infarct; S, small infarct; VL, very large infarct; nc, no change.

^b*p* < 0.05 as compared to vehicle.

that do not express the gene encoding the neuronal or endothelial NOS isoform (Huang *et al.*, 1994, 1996; Table II). This approach helped to elucidate the relative importance of the two or more opposing actions of NO generated by the isoforms during ischemia and reperfusion. The evidence will be reviewed below.

NO-Mediated Toxicity

NOS-containing neurons comprise 1–2% of all the neurons in the cerebral cortex, corpus striatum, and hippocampus; however, they extensively branch among neighboring neurons (Bredt *et al.*, 1991; Fischer and Kuljis, 1994). This configuration led to the idea that NOS neurons can kill bordering cells when they produce NO in excessive amounts (Bredt *et al.*, 1991; Dawson and Dawson, 1995). Interestingly, these neurons themselves are resistant to various insults, including NMDA toxicity, cell death in Huntington's disease, and ischemia (Koh and Choi, 1988; Uemura *et al.*, 1990; Gonzalez-Zulueta *et al.*, 1998).

NO may cause cytotoxicity by several mechanisms, including disruption of cellular metabolism, inhibition of DNA synthesis, and damage to DNA structure (Dawson and Dawson, 1995; Liu and Hotchkiss, 1995). DNA damage leads to activation of a DNA repairing enzyme, poly(ADP-ribose) polymerase (PARP), which consumes high amounts of ATP and NAD⁺ and may facilitate collapse of energy metabolism and cell death (J. Zhang *et al.*, 1994). In addition to promoting necrotic cell death, NO may cause death by an apoptotic process (Albina *et al.*, 1993; Ankarcrona *et al.*, 1994; Estevez *et al.*, 1995; Lin *et al.*, 1995). Formation of peroxynitrite (ONOO[–]) by interaction of NO with superoxide anion appears to be a major cell death mediator (Beckman and Koppenol, 1996; Beckman *et al.*, 1996; Kamii *et al.*, 1996). In a superoxide-rich environment, NO may also release intracellular iron, thereby triggering the Haber–Weiss reaction and formation of reactive oxygen species (Gross and Wolin, 1995).

NO and Cerebral Ischemia

Neurons, perivascular nerves, and cerebrovascular endothelium may generate NO during cerebral ischemia. It is likely that constitutive NOS activity increases during ischemia owing to a rise in intracellular Ca^{2+} . Constitutive NOS is activated by intracellular Ca^{2+} concentrations slightly above the resting level and is maximally stimulated at $0.5 \mu\text{M}$ (Knowles *et al.*, 1989), suggesting that it is fully active during focal ischemia, in which much higher Ca^{2+} levels are attained in neurons ($10\text{--}100 \mu\text{M}$). This hypothesis is supported by a striking increase in cortical NO levels from approximately 10 nM to $2.2 \mu\text{M}$ within 3 to 24 min after MCA occlusion (Malinski *et al.*, 1993). With use of the same porphyrinic microsensor technique, a rapid increase in nitric oxide was measured in femoral artery wall subjected to ischemia (from 50 to 450 nmol/liter) (Huk *et al.*, 1998). Brain nitrite (stable NO metabolite) and cGMP (a product of NO action) levels also rise within the first half hour of MCA occlusion (Kader *et al.*, 1993; Huang *et al.*, 1994). These increases are effectively blocked by prior L- N^{G} -nitroarginine administration, indicating enhanced NOS activity. Similar increases in NO (Olesen *et al.*, 1997) and in nitrate/nitrite levels (Togashi *et al.*, 1998; Rao *et al.*, 1998) have also been reported in global ischemia.

Constitutive NOS activity decreases shortly after its activation at the onset of ischemia (Kader *et al.*, 1993; Malinski *et al.*, 1993; Huk *et al.*, 1998). Depression of constitutive NOS activity was reported to continue up to 10 days following ischemia (Grandati *et al.*, 1997). It is possible that NOS activity may differ between the core and penumbra. Ohta *et al.* (1997) found a brief NO burst in areas where regional cerebral blood flow (rCBF) dropped to 9% of the basal level but a sustained enhancement in NO synthesis in areas where rCBF was 16%. Higher nitrotyrosine formation was detected in the penumbra than in the core region (Fukuyama *et al.*, 1998). It has been reported that nNOS generates NO in proportion to the O_2 concentration over an extremely wide range (Abu-Soud *et al.*, 1996). This feature enables nNOS to couple its rate of NO synthesis to the O_2 concentration. The nNOS isoform has an estimated K_{mO_2} of $\sim 400 \mu\text{M}$ (saturation at $\sim 800 \mu\text{M}$). In the absence of L-arginine, estimated K_{mO_2} is $\leq 40 \mu\text{M}$ (saturation at $\sim 100 \mu\text{M}$). Under conditions of arginine or tetrahydrobiopterin deficiency, NOS generates superoxide, which may directly contribute to toxicity or react with NO to form peroxynitrite (Abu-Soud *et al.*, 1996; Xia *et al.*, 1996). 3-Nitrotyrosine staining, reflecting peroxynitrite formation, was identified in ischemic tissue by immunohistochemistry (Eliasson *et al.*, 1999). A late but sustained increase in NO levels may also occur due to expression of inducible NOS within microglia, invading inflammatory cells, and cerebrovascular endothelium 24–72 hours after the induction of MCA occlusion (Iadecola *et al.*, 1995; Galea *et al.*, 1998).

During the immediate period following ischemia, NO production may improve blood flow and be neuroprotective.

Indeed, infusion of L-arginine dilates pial vessels via an NO-dependent mechanism, increases rCBF in normal as well as in ischemic brain, and reduces infarct size (Morikawa *et al.*, 1994). L-Arginine leads to electrocorticogram recovery if blood flow enhancement exceeds the functional flow threshold of approximately 30% of preischemic levels (Dalkara *et al.*, 1994). Importantly, L-arginine infusion did not augment blood flow in eNOS $-/-$ mice. However, this favorable action of L-arginine is not sustained during ischemia, owing to rapid inactivation of eNOS (Dalkara *et al.*, 1994; Kirsch *et al.*, 1997). Intracarotid administration of NO donor agents, on the other hand, leads to blood flow increases within the ischemic tissue for at least 1 hour after arterial occlusion and a decrease in infarct size in models of focal ischemia (F. Zhang *et al.*, 1994). In addition to its blood flow-enhancing effect, endothelial NO production may also improve microcirculation by reducing platelet aggregation and leukocyte adhesion (Niu *et al.*, 1994; Gidday *et al.*, 1998). Sodium nitroprusside was shown to improve rCBF in ischemic brain areas and inhibit platelet aggregation and adhesion molecule expression in stroke patients (Butterworth *et al.*, 1998). Selective eNOS upregulation might also provide a useful treatment strategy to enhance vascular NO production. 3-Hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (statins) have been shown to selectively upregulate endothelial NOS with an action independent of their cholesterol lowering effect, and they have been shown to confer protection in rodent stroke models (Endres *et al.*, 1998a). Supporting this idea, a clinical trial (CARE study) demonstrated that stroke incidence decreased by 31% in 4159 subjects treated chronically with pravastatin (Sacks *et al.*, 1996). Interestingly, a point mutation in the eNOS gene has been reported to be associated with coronary artery spasm (Yoshimura *et al.*, 1998).

Overproduction of NO by neurons during the early stages of ischemia may be detrimental to neuronal survival by accelerating cellular metabolism and/or damaging DNA. Peroxynitrite may be a major mediator of cell death (Beckman *et al.*, 1996; Kamii *et al.*, 1996; Endres *et al.*, 1998b; Forman *et al.*, 1998). A second wave of NO and peroxynitrite generation may take place during reperfusion if constitutive NOS is reactivated (Fukuyama *et al.*, 1998; Higuchi *et al.*, 1998). However, NO formation may also benefit the microcirculation during reperfusion. The net outcome, determined in part by duration and depth of ischemia, is impacted by NOS activity, L-arginine depletion, superoxide production, and formation of platelet and neutrophil aggregates.

Knockout Mice

Research since the 1980s has clearly documented the importance of genetically engineered mice as a promising tool for elucidating the importance of a targeted gene. Several mutant strains were generated in the 1990s (Thomas, 1995; Rubin and Barsh, 1996) by disruption of one (sometimes

two) of an estimated 50,000–100,000 mouse genes by homologous reconstitution (Fässler *et al.*, 1995). The majority of available mutants have “null” (or loss-of-function) alleles of the gene. Null mutants have been developed to study the role of proteins during development, in adult life, and in disease states. Surprisingly, many knockouts exhibit a normal phenotype, most likely owing to redundancy of genes compensating for the deleted gene product (e.g., Huang *et al.*, 1993). However, increasing evidence indicates that, despite an apparently normal phenotype, knockout animals may display conspicuous abnormalities in unanticipated tissues (e.g., Huang *et al.*, 1993) and respond differently than wild-type animals to various manipulations (e.g., Irikura *et al.*, 1995). They have been especially useful in confirming the pharmacological activity of drugs whose selectivity is in question. For example, basic fibroblast growth factor (bFGF) has been demonstrated to protect the brain against ischemia (Koketsu *et al.*, 1994; Fisher *et al.*, 1995; Jiang *et al.*, 1996). However, its mode of action was not clear because part of this protective effect might be due to its vasodilatory action and part might be due to trophic action, as suggested by the considerable neuroprotection obtained with its intracerebroventricular administration. Knockout mice that do not express the gene for eNOS helped to elucidate this controversy; they did not show cerebrovasodilation in response to bFGF administration, yet they developed significantly smaller infarcts when subjected to MCA occlusion (Huang *et al.*, 1997).

Neuronal NO Synthase Mutant Mice

Targeted disruption of the gene encoding nNOS was achieved using homologous recombination by substitution of a neomycin resistance gene for the first protein coding exon (Huang *et al.*, 1993). The mutant mouse develops normally, and the endothelium of nNOS knockouts expresses eNOS immunoreactivity (Irikura *et al.*, 1995). In nNOS mutants, neuronal NOS expression and NADPH diaphorase staining were markedly deficient, and *in vitro* NOS activity was significantly reduced (Huang *et al.*, 1993). Interestingly, alternative splice variants have been reported that generate NO *in vitro* but lack the PDZ-containing domain and potential coupling to the NMDA receptor (Brenman *et al.*, 1996; Eliasson *et al.*, 1997a). However, the expressed splice variants do not compensate sufficiently, as NOS activity in nNOS $-/-$ brains is severely reduced (<5 –8% of normal). Consistent with this, low basal levels of L-N^G-[³H] nitroarginine binding (Hara *et al.*, 1997) and brain cGMP levels were found in mutants, and no cGMP enhancement was observed during ischemia or hypercapnia, contrary to the robust increases in wild-type mice (Huang *et al.*, 1994; Irikura *et al.*, 1995). Consistent results were also obtained by NMR spectroscopy, as NO adducts were undetectable during cerebral ischemia as measured in nNOS null mice (Mullins *et al.*, unpublished observations). Regional cerebral blood flow responses to hypercapnia (Irikura *et al.*, 1995) and to whisker

stimulation (Ma *et al.*, 1996) and pial arterial dilation to topical acetylcholine (ACh) superfusion (Meng *et al.*, 1996) were not significantly different from wild-type mice, although these were markedly reduced after administering NOS inhibitors.

Neuronal NO Synthase Mutant Mice and Cerebral Ischemia

The deficiency in neuronal NO production is associated with increased resistance to cerebral ischemia. The nNOS knockouts develop infarcts 38% smaller than the wild-type mice when subjected to 24-hour permanent MCA occlusion (Huang *et al.*, 1994). Infarct size is also reduced in mutants 3 to 4 days after permanent MCA occlusion. Neurological deficits are less in nNOS knockout mice. Because reductions in regional cerebral blood are similar within homologous ischemic regions after MCA occlusion in both groups, the observed group differences were attributed to the consequence of neuronal NOS deletion in brain tissue and not to hemodynamic differences between strains.

Infarcts were 69% smaller in nNOS knockouts than in wild-type mice in animals subjected to 3 hours of ischemia and 24 hours of reperfusion (Hara *et al.*, 1996). Brain protection was greater than after permanent occlusion, possibly due to greater superoxide anion production during reversible occlusion (Chan *et al.*, 1993; Yang *et al.*, 1994; Chan, 1996). Interestingly, quantitative L-N^G-[³H]nitroarginine autoradiography demonstrated a significant increase (50–250%) in the density of L-N^G-[³H]nitroarginine binding sites (B_{\max}), but not the dissociation constant (K_d), during transient focal ischemia and first 3 hours of reperfusion (Hara *et al.*, 1997). nNOS mRNA was also increased as detected by reverse transcription–polymerase chain reaction. As noted earlier, L-N^G-[³H]nitroarginine binding to nNOS protein was very low in nNOS mutant mice, and only a very small increase was observed after ischemia or NMDA excitotoxicity.

nNOS mutants are also more resistant to global ischemia (Panahian *et al.*, 1996). Fewer dead hippocampal neurons were counted 3 days after transient global ischemia induced by bilateral common carotid plus basilar artery occlusion for 5 or 10 min. Not only were more hippocampal cells viable, but overall morbidity, weight loss, and neurological outcome were better in the mutant strain.

Endothelial NO Synthase Mutant Mice and Cerebral Ischemia

Consistent with the evidence just given, larger infarcts developed in eNOS knockout mice after 24-hour permanent MCA occlusion (Huang *et al.*, 1996). Deletion of eNOS rendered these mutants hypertensive (Huang *et al.*, 1995). However, hypertension per se did not account for the increased susceptibility of eNOS mutants, because infarct size did not

decrease after blood pressure was reduced by hydralazine (Huang *et al.*, 1996). eNOS mutants developed more pronounced rCBF reductions in corresponding brain regions after MCA occlusion and exhibited proportionally lower rCBFs at reduced perfusion pressures during controlled hemorrhagic hypotension (Huang *et al.*, 1996). Dynamic computerized tomography (CT) scanning demonstrated that areas of hemodynamic penumbra were significantly smaller and the core relatively larger in eNOS mutants (Lo *et al.*, 1996). Hence, the susceptibility of eNOS mutants to ischemic injury may be due to its diminished capacity to adapt to reduced perfusion pressure (i.e., dilate) at the margins of an ischemic lesion. This, coupled with enhanced platelet and neutrophil adhesion, renders eNOS mutants more susceptible to injury. Consistent with this notion, L-^N^G-nitroarginine administration increased infarct size in the nNOS knockout mouse, presumably due to inhibition of the constitutively expressed eNOS isoform (Huang *et al.*, 1996). Neuroprotection was obtained in ischemic injury after administering selective nNOS inhibitors, 7-nitroindazole (Yoshida *et al.*, 1994), ARL17477 (Zhang *et al.*, 1996), or 1-(2-trifluoromethylphenyl) imidazole (Escott *et al.*, 1998).

Poly(ADP-Ribose) Polymerase Activation and NO in Cerebral Ischemia

As noted earlier, one candidate pathway for NO-mediated neuronal injury is DNA damage leading to the obligatory activation of the nuclear enzyme PARP. PARP is activated in ischemic brain within minutes after reperfusion following MCA occlusion, as evidenced by poly(ADP-ribose) immunohistochemistry. Poly(ADP-ribose)-positive cells show signs of early ischemic damage. NAD⁺ levels as shown by *in situ* histochemistry become depleted in the MCA territory (Endres *et al.*, 1997). Inhibition of PARP activation or disruption of the PARP gene (PARP knockouts) confers protection after brain ischemia (Endres *et al.*, 1997; Eliasson *et al.*, 1997b). Consistent with this protection, poly(ADP)ribose formation is inhibited and NAD⁺ levels are significantly higher in these animals, demonstrating an energy-preserving neuroprotective mechanism. Total DNA damage, upstream to PARP activation in the cascade, is not affected by PARP inhibition or gene deletion (Endres *et al.*, 1997).

We further established the importance of NO to the PARP activation pathway *in vivo* by evaluating poly(ADP-ribose) formation in nNOS knockout animals. Following a 2-hour MCA occlusion and reperfusion, nNOS knockout animals exhibited strikingly less poly(ADP-ribose)-positive cells compared to their littermate controls (Endres *et al.*, 1998b). Moreover, the density of TUNEL (terminal deoxynucleotidyl transferase-mediated dUTP-biotin nick end-labeling)-positive cells is decreased after ischemia in nNOS knockout mice, indicating less DNA damage (see also next paragraph). Thus, decreased DNA damage and subsequent PARP activation may confer resistance to ischemic brain damage in

nNOS knockout animals. Endres *et al.* (1998b) also tested in glioma cells whether NO or peroxynitrite was the actual trigger of PARP activation. Peroxynitrite, but not various NO donor agents, activated PARP and suppressed cellular viability in a PARP-dependent fashion.

NO-Induced Apoptotic Cell Death

At least two mechanistically distinct forms of neuronal death have been identified. Severely injured neurons that do not immediately die by swelling and lysis may ultimately undergo apoptosis. Apoptotic neuronal death contributes to infarct formation in cerebral ischemia (Li *et al.*, 1995; Charriaut-Marlangue *et al.*, 1996; MacManus and Linnik, 1997). NMDA, or concurrent generation of nitric oxide and superoxide, can cause both necrosis and apoptosis, depending on the severity of the insult and resulting mitochondrial dysfunction (Bonfoco *et al.*, 1995; Ankarcrona *et al.*, 1995). Both NO and ONOO⁻ have been linked to apoptosis (Ankarcrona *et al.*, 1994; Estevez *et al.*, 1995; Keller *et al.*, 1998). Because blockade of neuronal NO synthesis proves to be neuroprotective in focal and global cerebral ischemia and NMDA toxicity *in vivo*, it is important to understand the extent to which NO-induced apoptosis contributes to neuronal death under these pathological conditions.

We compared the number of apoptotic cells in wild-type and nNOS mutant mice 6, 24, and 72 hours after permanent MCA occlusion by filament. TUNEL-positive neurons were detected at 6 hours and continued to increase by 72 hours. These cells were detected in both penumbra and core regions, but most were located on the inner boundary zone of the infarct. Numbers of apoptotic cells as well as their densities were significantly lower in nNOS mutants, suggesting a selective decrease in the number of TUNEL-positive cells. Such findings support the notion that NO and its reaction products promote apoptosis as a mechanism of cytotoxicity, as suggested by studies reporting apoptotic cell death after application of NO or peroxynitrite (Ratan *et al.*, 1994; Estevez *et al.*, 1995; Bonfoco *et al.*, 1995; Palluy and Rigaud, 1996; for review, see Nicotera *et al.*, 1995). Precisely how the development of apoptosis in ischemia relates to caspase activation (Namura *et al.*, 1998) and cleavage of PARP remains for further study.

NITRIC OXIDE (NO) HAS REVOLUTIONIZED OUR PERCEPTION OF NEUROTRANSMISSION AND NEURONAL SIGNALING. NO IS EMERGING AS A KEY REGULATOR OF NUMEROUS PHYSIOLOGICAL RESPONSES. HOWEVER, EXCESSIVE GENERATION OF NO CAN MEDIATE NEURONAL DAMAGE IN A VARIETY OF NEUROLOGIC DISEASES. UNDERSTANDING THE PATHWAYS THROUGH WHICH NO CAUSES NEURONAL CELL DEATH IS KEY IN THE DEVELOPMENT OF MORE EFFECTIVE THERAPIES. IN THIS CHAPTER WE REVIEW THE CURRENT KNOWLEDGE ON THE MECHANISMS OF NO-MEDIATED NEUROTOXICITY. A PROMINENT PATHWAY THROUGH WHICH NO DAMAGES NEURONS IS THE REACTION WITH THE SUPEROXIDE ANION TO GENERATE PEROXYNITRITE. PEROXYNITRITE IS A POTENT CELLULAR TOXIN AND IS CAPABLE OF ALTERING PROTEINS, LIPIDS, AND DNA. EXCESSIVE ACTIVATION OF THE DNA REPAIR ENZYME POLY(ADP-RIBOSE) POLYMERASE (PARP), WHICH MAY LEAD TO CELL DEATH THROUGH DEPLETION OF THE CELLULAR ENERGY STORES, HAS EMERGED AS AN IMPORTANT MEDIATOR OF NO-INDUCED NEUROTOXICITY. NO MAY INTERACT DIRECTLY WITH A LARGE NUMBER OF PROTEINS AND CAUSE SUBSEQUENT ALTERATION OF THEIR FUNCTION. NO-INDUCED CELL DEATH IS CHARACTERIZED BY TYPICAL FEATURES OF BOTH NECROSIS AND/OR APOPTOSIS. NO PLAYS A ROLE AS A NEURONAL CELL DEATH MEDIATOR IN A VARIETY OF DISORDERS OF THE NERVOUS SYSTEM. IN THIS CHAPTER WE DISCUSS THE INVOLVEMENT OF NO IN EXCITOTOXICITY, STROKE, ISCHEMIC PRECONDITIONING, AND PARKINSON'S DISEASE.

Introduction

Since its initial discovery, nitric oxide (NO) has become one of the most highly studied and important bioactive molecules. Along with the many essential roles of nitric oxide *in vivo*, such as neurotransmission, vasodilation, and immune defense, it can also be involved in reactions that may result in cell damage and death. NO is a relatively unstable molecule that is potentially toxic owing, in part, to the high reactivity of its unpaired electron. It has long been studied as an environmental pollutant because it contributes to the formation of smog, and acid rain and is also involved in the destruction of the ozone layer (Feldman *et al.*, 1993), so it was

surprising when NO was found to play an important role in mammalian physiology. NO is biologically relevant because of its production by numerous cell types and because of its role in many physiological processes. In fact, virtually every type of mammalian cell is under the influence of NO (Schmidt and Walter, 1994). NO is synthesized by one of three distinct NO synthase (NOS) isoforms. Depending on the site of production, the amount of NO produced, and the targets within the local environment, NO can exert many diverse functions. In the nervous system, NO has a dual role as a physiological messenger and a mediator of lethal processes in a variety of neurodegenerative disorders and toxic insults of the nervous system.

The Unique Characteristics of Nitric Oxide

The enzymatic combination of a single atom of nitrogen with a single oxygen atom forms the smallest synthetic product of mammalian cells. It also forms a molecule with an unpaired electron in a frantic search for another molecule to accept or share this odd electron (Nathan, 1992). Target molecules include oxygen, other free radicals, thiol groups, and metals. In an environment rich in these targets, NO has a short half-life, in the range of a few seconds or less. Whereas NO can be inactivated through its interaction with oxygen to form nitrite and nitrate, the interaction of NO with other free radicals is a mechanism by which NO exerts many of its effects. The combination of NO with superoxide (O_2^-) forms peroxynitrite ($ONOO^-$) with the capacity to injure target cells. When NO interacts with prosthetic iron groups or thiol groups on proteins, it can form complexes that activate or inactivate target enzymes. It is through this mechanism that NO activates one of its main target enzymes, soluble guanylate cyclase, which increases cellular cGMP concentrations. The heme-dependent activation of this enzyme by NO results in vasorelaxation in the vasculature and neurotransmission in the central nervous system. Under conditions of high NO formation, a variety of enzymes can also be inhibited by NO-enzyme interaction (Feldman *et al.*, 1993; T. M. Dawson *et al.*, 1994; Garthwaite and Garthwaite, 1994). For example, the glycolytic enzyme glyceraldehyde-3-phosphate dehydrogenase is inactivated by nitrosylation of a thiol group in its active site (Molina y Vedia *et al.*, 1992), whereas aconitase in the Krebs cycle and nicotinamide adenine dinucleotide (NADH):ubiquinone oxidoreductase in the mitochondrial electron transport chain are inhibited when peroxynitrite attacks the iron atom in the iron-sulfur cluster essential to the functions of these enzymes (Stuehr and Nathan, 1989). The inactivation of these and other enzymes is believed to be the mechanism by which cytokine-induced NO can inhibit the growth of target cells such as microorganisms, tumor cells, or lymphocytes.

The action of NO is mostly local; however, NO has the capacity to move rapidly to sites of target molecules. Unlike many messenger molecules and secretory molecules that use membrane receptors or specific membrane transporters, NO is so lipophilic that it readily diffuses across membranes. Thus, NO is a unique messenger that rapidly moves cell to cell, with a short range and duration of action, but exhibiting high biological activity.

Nitric Oxide Synthase Isoforms

In biological systems the amino acid L-arginine is the sole substrate for NO synthesis. L-Arginine contains two guanidine nitrogens that accept five electrons in an oxidation-reduction pathway which results in the stoichiometric formation of L-citrulline and NO (Nathan, 1992). This reaction is carried out by one of three isoforms of nitric oxide synthase (NOS), which are named after the tissue from which

they were first cloned and numbered in the order in which they were cloned (T. M. Dawson *et al.*, 1998). Neuronal NOS (nNOS or type I) and endothelial NOS (eNOS or type III) are constitutively expressed and are calcium dependent; inducible NOS (iNOS or type II) is expressed after immunological challenge and neuronal injury and is calcium independent under most circumstances (T. M. Dawson *et al.*, 1998).

In vitro biochemical studies have indicated that NOS activity is regulated by the phosphorylation state of the enzyme. Phosphorylation of NOS by protein kinase C, cAMP-dependent protein kinase, or Ca^{2+} /calmodulin-dependent protein kinase inhibits its catalytic activity (Dinerman *et al.*, 1994a), whereas dephosphorylation enhances its activity (T. M. Dawson *et al.*, 1993).

The synthesis of NO can be inhibited by L-arginine analogs such as N^G -monomethyl-L-arginine (L-NMMA), N^G -nitro-L-arginine (L-NA), or N^G -nitro-L-arginine methyl ester (L-NAME) that compete for binding at the NOS catalytic site (Kerwin *et al.*, 1994). Calmodulin antagonists and gangliosides are also potent inhibitors of NOS catalytic activity (T. M. Dawson *et al.*, 1995). These agents inhibit all NOS isoforms. More selective NOS inhibitors have been developed. For instance, 7-nitroindazole (7-NI) was the first relatively selective nNOS inhibitor developed (Babbedge *et al.*, 1993). Although *in vitro* 7-NI inhibits all three isoforms with equal affinity, *in vivo* it has marked selectivity for inhibition of nNOS over eNOS and, thus, has minimal vascular effects. Aminoguanidine is relatively selective for iNOS, and it has been extensively used *in vivo* (Arkovitz *et al.*, 1996; Higuchi *et al.*, 1998; Zhang and Iadecola, 1998). Despite the wide use of aminoguanidine, caution must be used when interpreting experiments because aminoguanidine is a potent inhibitor of diamine oxidase, polyamine oxidase, and ribonucleotide reductase, and it is also a general oxidase, decarboxylase, and catalase inhibitor, as well as an inhibitor of advanced glycosylation end products. The isothioureas in general are potent and selective inhibitors of iNOS, and these agents have been widely used to study the role of iNOS-produced NO in the pathophysiology of inflammation (Jang *et al.*, 1996) and circulatory shock (Thiemermann *et al.*, 1995; Arkovitz *et al.*, 1996). Highly selective nNOS inhibitors have been developed and include ARL-17477 and A-84643 (Z. Zhang *et al.*, 1996); also, analogs of 2-iminohomopiperidinium have been reported to be potent and selective inhibitors of iNOS catalytic activity (Hansen *et al.*, 1998).

All three NOS isoforms have been identified in numerous tissues. Except for a few isolated regions, such as the cerebellum, where nNOS is expressed in most of the granule cells, nNOS expression in the brain is restricted to certain subpopulations of neurons throughout the brain. For instance, nNOS neurons represent about 1 to 2% of the total neuronal population in the cortex and corpus striatum (Bredt *et al.*, 1990). In these regions, nNOS neurons colocalize with somatostatin and neuropeptide Y (T. M. Dawson *et al.*, 1991). In the hippocampus, pyramidal cells of the CA1 re-

gion do not express nNOS or express barely detectable levels, whereas eNOS (Dinerman *et al.*, 1994b) is highly expressed. Both isoforms have been detected in the same neurons in some regions of the cerebellum and olfactory bulb. Several splice variants of nNOS have been identified. Significant structural diversity of nNOS occurs through alternative splicing. Alternative splicing of exon 2 was first noted during the characterization of mice lacking the gene for nNOS in which exon 2 was targeted. Characterization of residual NOS catalytic activity in nNOS null mice revealed that the residual activity was due to alternative nNOS isoforms designated nNOS- β and nNOS- γ (Brenman *et al.*, 1996a). Contained within exon 2 of nNOS is a PDZ domain that may mediate binding of nNOS to synaptic junctions through interactions with postsynaptic density proteins (PSD) (Brenman *et al.*, 1996b). In the nervous system, nNOS is closely associated with *N*-methyl-D-aspartate (NMDA) receptors, probably through PDZ interaction domains of each protein. The lack of the amino terminus of nNOS would prevent the association of nNOS in postsynaptic density, leading to the potential inability to be stimulated by increases in intracellular calcium mediated by NMDA receptor activation. Consistent with this notion is the loss of NMDA-stimulated NO formation in nNOS null mice (V. Dawson *et al.*, 1996). Sattler *et al.* (1999) indicate that disruption of nNOS interactions with PSD-95 uncouple NMDA receptor activity from NO toxicity and thus imparts specificity to excitotoxic calcium signaling.

Mechanisms of Nitric Oxide-Mediated Cytotoxicity

The exact pathways by which excessive NO production causes neuronal death are not known. Disruption of any of the physiological processes in which NO is involved could potentially have deleterious consequences for neuronal survival. Although the exact pathways through which NO causes neuronal death remain controversial, several general mechanisms have been proposed (Garthwaite and Boulton, 1995; Yun *et al.*, 1996; Bolanos *et al.*, 1997; T. M. Dawson *et al.*, 1998). It is felt that the generation of peroxynitrite by the reaction of NO with superoxide accounts for most of the toxicity elicited by NO, although other direct targets of NO have been proposed.

Targets of Nitric Oxide

Although NO is an important and unique messenger molecule, it also plays pathological roles in excitotoxicity, stroke, migraine, epilepsy, and neurodegenerative diseases. Models of potential diffusion of NO indicate that it can diffuse as far as 300 μm from its site of origin, which could include as many as 2 million synapses (Wood and Garthwaite, 1994).

Because of an unpaired electron, NO is a free radical, and its effects are largely mediated through other molecules that accept or share this odd electron (T. M. Dawson *et al.*, 1998).

Table I Reactions of Nitric Oxide^a

Reaction with molecular oxygen	
$2\text{NO}\cdot + \text{O}_2 \rightleftharpoons 2\text{NO}_2\cdot$

^aModified from T. M. Dawson *et al.* (1998).

Target biological molecules include oxygen, other free radicals, thiol groups, and metals (Table I).

There are two well-characterized reactions of NO *in vivo*. The first reaction is with oxyhemoglobin to form methemoglobin and nitrate, which is considered the principal mechanism for NO clearance *in vivo* (Liebler *et al.*, 1998). NO generated by NO-donating compounds *in vitro* can accumulate at micromolar concentrations and lead to formation of $\text{NO}_2\cdot$ and N_2O_3 via reactions with oxygen. Generation of 10 $\mu\text{M}/\text{min}$ of NO *in vivo* with a half-life of 1 s and with detoxification by oxyhemoglobin can produce steady-state NO levels of 0.2 μM . This leads to approximately one NO molecule in 10,000 reacting with oxygen to form $\text{NO}_2\cdot$, while the rest is converted to nitrate by oxyhemoglobin.

The second key reaction of NO *in vivo* is its interaction with superoxide ($\text{O}_2^{\cdot-}$) to form peroxynitrite (ONOO^-), which occurs with a second-order rate constant of $6.7 \times 10^9/\text{M}\cdot\text{s}$. A key consideration in the fate of reactive oxygen species is the presence of biologically relevant levels of antioxidant defense. For example, superoxide dismutases (SODs) in the brain are present at a cellular concentration of 5–10 μM , which maintains superoxide at a steady-state level of about 10 pM. The reaction of NO and $\text{O}_2^{\cdot-}$ is about seven or eight times faster than scavenging by SODs under physiological conditions, even though there is approximately a million times more SOD than $\text{O}_2^{\cdot-}$ at the physiological steady state. *In vivo*, concentrations of NO generally exceed those of $\text{O}_2^{\cdot-}$ because of $\text{O}_2^{\cdot-}$ consumption by SOD. Peroxynitrite is a relatively stable molecule and can diffuse a few micrometers in half of its biological half-life; thus, it can cross membranes. It can survive millions of collisions with thiols and other biological reductants before reacting. This allows peroxynitrite to survive to react with targets toward which it is highly reactive, such as the iron–sulfur cluster of proteins and zinc fingers. Selective oxidants, such as peroxynitrite, can ultimately be more toxic than more highly reactive oxidants, such as hydroxyl radical ($\cdot\text{OH}$).

A predominant mechanism by which NO kills neurons is through the diffusion-limited reaction of NO with O_2^- to generate ONOO⁻ (Beckman *et al.*, 1990), which is directly cytotoxic (Beckman and Crow, 1993). Peroxynitrite has the activity of the free radicals $\cdot OH$ and NO_2 ; although it may not decompose directly into these species. It nitrates and hydroxylates aromatic rings on amino acid residues, and it is also a potent oxidant that reacts readily with sulfhydryls, zinc-thiolate moieties, lipids, proteins, and DNA (Molina y Vedia *et al.*, 1992; Crow *et al.*, 1995). Most likely, peroxynitrite mediates the interactions of NO with the iron-sulfur cluster of proteins, inhibits DNA synthesis by ribonucleotide reductase, liberates iron by binding to the iron in ferritin, and influences iron metabolism at the posttranscriptional level by interacting with aconitase. In the presence of ONOO⁻, aconitase activity is disrupted and its RNA binding site exposed, leading to the enzyme function as the iron-responsive binding protein which binds to the iron-responsive element (Weiss *et al.*, 1993, 1994; V. L. Dawson and T. M. Dawson, 1996).

Protein Modification

Reactions of NO with amino acid residues include nitrosation (formation of nitrosamines, nitrosothiols, and deaminations) and oxidation via peroxynitrite. The balance between these effects is dictated by competition between reaction pathways that lead to the formation of more reactive nitrogen oxides (e.g., reaction with oxygen to form N_2O_3), formation of peroxynitrite, trapping of free radicals, and interaction with metals and metalloproteins.

A key interaction is the binding of NO to the heme of guanylate cyclase (Table II), which elicits many of the well-known physiological actions of NO. NO combines with non-heme iron in a variety of enzymes, including NADPH-ubiquinone oxidoreductase, NADH-succinate oxidoreductase, and *cis*-aconitase, which are all iron-sulfur enzymes, resulting in enzyme inactivation (Zhang and Snyder, 1995). NO binds to the iron in ferritin, liberating iron that can result in lipid peroxidation. Other targets of NO include cytochrome *c* oxidase in the mitochondrial respiratory chain, ribonucleotide reductase (the rate-limiting enzyme in DNA synthesis), and glyceraldehyde-3-phosphate dehydrogenase in the glycolytic pathway. NO can also modify protein function by S-nitrosylation of target molecules such as p21^{ras}, protein kinase C, and glyceraldehyde-3-phosphate dehydrogenase (Dimmeler *et al.*, 1992; Stamler *et al.*, 1992; Lander *et al.*, 1995).

DNA Damage

DNA damage can occur by the actions of N_2O_3 or peroxynitrite. N_2O_3 can damage DNA directly by deamination of cytosine to uracil, and indirectly by inactivation of DNA repair enzymes such as *O*⁶-alkylguanine transferase. NO exposure can also lead to the formation of single-strand breaks in DNA both *in vitro* and *in vivo* (Burney *et al.*, 1998). In

DNA deamination
DNA strand breaks

^aModified from T. M. Dawson and V. L. Dawson (1999).

contrast to NO, which is involved primarily in the deamination chemistry of DNA, most of the damage inflicted on DNA by peroxynitrite is oxidative (Burney *et al.*, 1998). DNA treatment with peroxynitrite generally leads to much more damage than treatment with an equivalent dose of NO. Not only are the levels of damage higher, but also the spectrum of alterations tends to be much more complex (Burney *et al.*, 1998).

DNA damage by NO \cdot /ONOO⁻ leads to subsequent activation of the enzyme poly(ADP-ribose) polymerase (PARP) (J. Zhang *et al.*, 1994; V. L. Dawson and T. M. Dawson, 1996). PARP is a nuclear enzyme involved in DNA repair (Lautier *et al.*, 1993). It is activated by breaks in DNA, and it catalyzes the transfer of ADP-ribose to nuclear proteins such as histone and PARP itself. The addition of ADP-ribose groups to nuclear proteins by PARP facilitates separation of the DNA strands and improves access for the DNA repair enzymes. PARP can add hundreds of ADP-ribose units within seconds to minutes of being activated (Lautier *et al.*, 1993; de Murcia and Menissier de Murcia, 1994). For every mole of ADP-ribose transferred by PARP, one mole of NAD and four free energy equivalents of ATP are consumed. Therefore, activation of PARP can rapidly deplete cellular energy stores. If this depletion is severe and sustained, it can

lead to impaired cellular metabolism and ultimately to cell death. In fibroblasts from mice where the PARP gene has been knocked out, apoptotic death is accelerated due to impaired DNA repair mechanisms (de Murcia *et al.*, 1994). However, in some cell lines genetic knockout of PARP has no evident effect on apoptotic cell death (Wang *et al.*, 1997). Compelling evidence for the involvement of PARP in NO-mediated toxicity was provided by studies on mice with a targeted disruption of PARP (Heller *et al.*, 1995). Islet cells lacking PARP do not show DNA damage-induced energy depletion and are more resistant to NO toxicity. However, NO-mediated toxicity was not completely abolished in the islet cells from mutant mice, which suggests the existence of alternative pathways for NO-mediated toxicity not involving PARP-induced NAD depletion. In neurons and myocytes, lack of PARP protects them dramatically against ischemic damage (Eliasson *et al.*, 1997; Endres *et al.*, 1997), and neuronal cultures from PARP knockout mice are remarkably resistant to excitotoxicity and NO toxicity (Eliasson *et al.*, 1997) (Fig. 1). The link between NO toxicity and PARP activation is a very important extension to the understanding of NO-induced neuronal damage, but an important unanswered question is how PARP activation relates to other downstream mechanisms implicated in neurotoxicity, including mitochondrial dysfunction (White and Reynolds, 1996).

Nitric Oxide and Mitochondria in Neurodegeneration

Increasing evidence suggests that dysfunction of cellular energy production is an important mechanism in NO-mediated neurotoxicity (Bolanos *et al.*, 1997). Mitochondrial complexes II–III and IV and succinate dehydrogenase are damaged in neurons and glia after NO exposure (Bolanos *et al.*, 1997). Also, NO is able to bind to mitochondrial complex I and II and inhibit oxidative phosphorylation. In addition, NO competes with oxygen for cytochrome oxidase, leading to reversible inhibition of mitochondrial respiration (Brown, 1995). Brorson *et al.* (1999) suggest that NO directly impairs mitochondrial function and energy metabolism in cultured hippocampal neurons. NO is capable of depolarizing the mitochondrial membrane potential, which is accompanied by a progressive concentration-dependent depletion of cellular ATP. Interestingly, the severe ATP-depleting effects of NO are not fully explained by the direct effects on mitochondrial activity, as inhibitors of mitochondrial oxidative phosphorylation such as rotenone or 3-nitropropionic do not mimic the effects of NO. Thus, the ATP-depleting effects of NO are not only related to its disruption of mitochondrial respiration, but also may be related to its effects on glycolysis or activation of PARP.

Mitochondrial failure results in increased free radical formation and membrane depolarization due to dysfunction of Na⁺, K⁺-ATPase, and this in turn promotes calcium influx through NMDA receptors, leading to maintained elevation of intracellular calcium concentration and NOS activation,

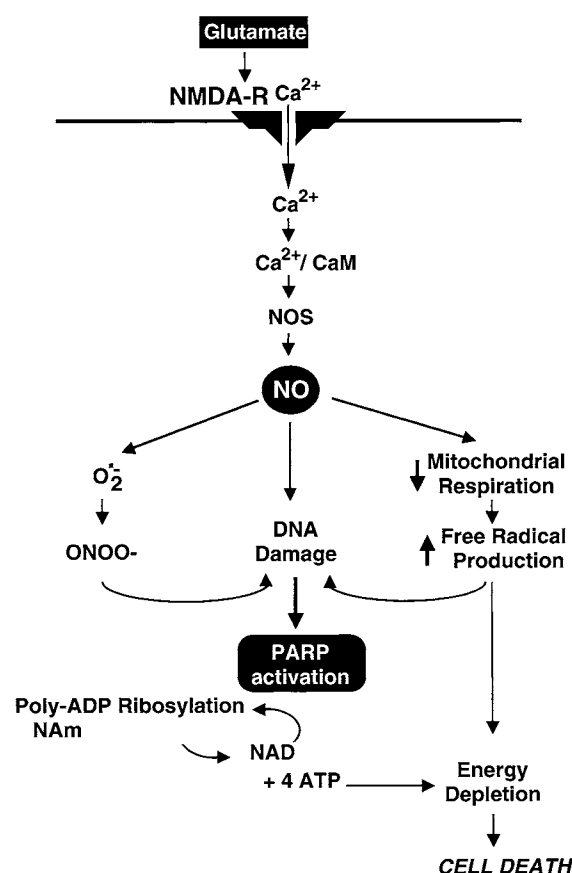

Figure 1 Mechanisms of PARP-mediated neuronal cell death in excitotoxicity. NMDA receptor (NMDA-R) activation causes an increase in intracellular calcium levels, which activates NOS. Excessive generation of NO leads to production of free radicals, mitochondrial dysfunction, and DNA damage. The damaged DNA activates PARP, which transfers ADP-ribose groups to nuclear proteins, consuming one mole of NAD. NAD is resynthesized from nicotinamide (NAM), a reaction that utilizes four high-energy equivalents of ATP. PARP adds ADP-ribose groups to numerous nuclear proteins, consuming a very large amount of energy. It is hypothesized that excitotoxicity-generated free radicals such as NO activate a futile cycle of DNA damage followed by PARP activation, which depletes cells of their energy stores, ultimately leading to cell death.

which could result in a self-propagating destructive cycle. Defects in mitochondrial energy metabolism have long been considered to underlie the pathology of neurodegenerative disorders (Beal *et al.*, 1993). For instance, decreased complex I activity has been reported in the substantia nigra of postmortem samples obtained from patients with Parkinson's disease, and impaired complex IV activity has been noted in Alzheimer's disease (Bolanos *et al.*, 1997).

Role for Nitric Oxide in Apoptosis

Although the term apoptosis was originally coined to describe defined morphological alterations, it is now generally used to describe the evolutionally conserved pathway of biochemical and molecular events leading to cell demise (Hale *et al.*, 1996; Leist and Nicotera, 1997). The term pro-

grammed cell death is now used as a synonym for apoptosis in appreciation of the genetic programs that regulate cell death (Vaux and Strasses, 1996).

NO-dependent apoptotic cell death was initially shown in peritoneal macrophages following immunological activation (Albina *et al.*, 1993; Sarih *et al.*, 1993). Evidence for apoptosis was provided by microscopic examination of chromatin condensation and by a specific pattern of internucleosomal DNA fragmentation. The involvement of NO was confirmed by the cell death-preventive effects of L-arginine-restricted medium and of the NOS inhibitor *N*^G-monomethyl-L-arginine, and more directly by exposing cells to NO gas, leading to apoptosis. Following these initial reports numerous studies have confirmed the ability of NO to initiate apoptosis in a variety of cell types and cell lines (Brune *et al.*, 1998), including neurons (Lipton *et al.*, 1993). Apoptotic cell death as a result of excessive NO production correlates with upregulation of the p53 tumor suppressor gene, activation of caspases, chromatin condensation, and DNA fragmentation (Brune *et al.*, 1998). The p53 tumor suppressor has come to be known as the master guardian of the genome and as a member of the DNA damage response pathways (Oren, 1997), and it induces growth arrest or apoptosis in DNA-damaged cells. Another mechanism by which NO may activate apoptosis is the activation of caspases, a family of cysteine proteases that specifically cleave a growing number of cellular substrates after Asp residues (Cohen, 1997). Caspase activation is inherent to the final executive phase of apoptosis. Some reports have shown that during NO-mediated apoptosis there is cleavage of PARP, which is an established caspase-3 substrate (Messmer *et al.*, 1998), and caspase activation by NO donor agents has been confirmed in human leukemia cells (Yabuki *et al.*, 1997), mesangial cells (Sandau *et al.*, 1997), and neuronal excitotoxicity (Leist *et al.*, 1997). It has been suggested that ceramide generation might be a mediator of NO signaling during apoptosis through caspase-3 activation (Takeda *et al.*, 1999).

In contrast to the proapoptotic role of NO, exposure to NO donor agents and activation of NOS have been reported to inhibit apoptosis in T lymphocytes and human umbilical vein endothelial cells (Mannick *et al.*, 1997) through cGMP-dependent actions, or by direct inhibition of caspase-3 through S-nitrosylation of cysteine-163, a key residue for caspase activity (Dimmeler *et al.*, 1997). The discrepancy in the NO effect on apoptosis may be due to differences in intensity and duration of NO exposure and the cellular environment. Indeed, low concentrations of NO donor agents (<100 μ M) show a protective effect against apoptosis, whereas induction of apoptosis is observed with >250 μ M NO donor agents (Takeda *et al.*, 1999). NO at low levels has the potential to modulate caspase activity, which is a further indication of the complexity of the cellular response to death signals. The current view on the role of NO in apoptosis is that low concentrations of NO are protective against apoptosis, whereas high NO concentrations induce apoptosis (Fig. 2).

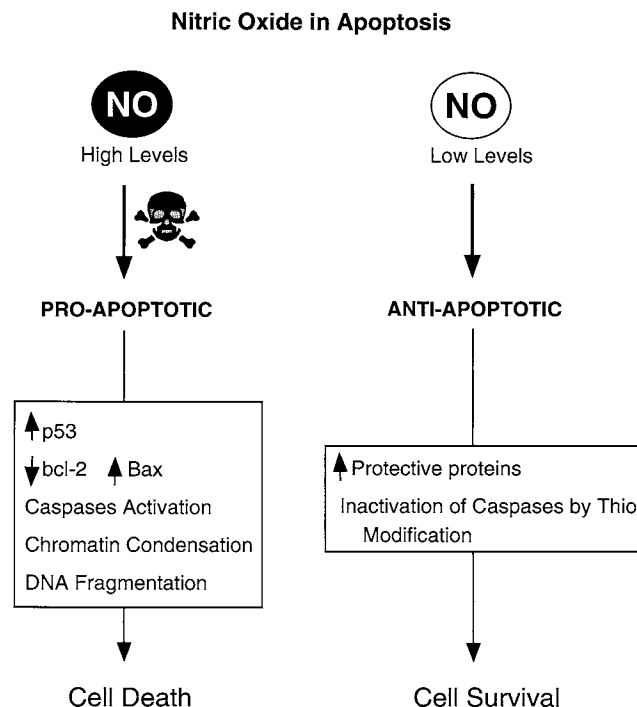

Figure 2 The dual role of NO in apoptotic cell death. The toxicity of NO is influenced by the existing biological milieu. Relative rates of NO formation, its oxidation and reduction, and the combination with oxygen, superoxide, and other molecules will determine the signaling pathway(s) initiated by NO. Large amounts of NO promote cell death, which is characterized by typical biochemical and morphological features that resemble apoptosis. Apoptosis associated with high NO levels is accompanied by an early accumulation of the tumor suppressor p53, decreased B-cell leukemia/lymphoma-2 (bcl-2) expression, upregulation of Bax, as well as activation of caspase-3, chromatin condensation, and DNA fragmentation. In contrast to its toxic effects at high levels, NO at low levels signals cell protection and has an antiapoptotic effect. Mechanisms that mediate the protective effect of NO include inhibition of caspase activity as well as activation of signaling pathways that mediate cell survival through the upregulation of protective proteins.

Neuronal Nitric Oxide Synthase Neurons Are Resistant to Toxic Insults

In 1961, Thomas and Pearse described a histochemical stain, NADPH diaphorase, that was detected in a unique subpopulation of neurons that comprises approximately 1–2% of the total neuronal population. Over the years, investigators have observed that these NADPH diaphorase-positive neurons are uniquely resistant to a variety of toxic insults. Thus, nNOS neurons are relatively spared from cell death in NMDA neurotoxicity, Huntington's disease, Alzheimer's disease, and vascular stroke (Ferrante *et al.*, 1985; Koh *et al.*, 1986; Choi, 1988; Uemura *et al.*, 1990; Hyman *et al.*, 1992). With the cloning and expression of nNOS, it was appreciated that this NADPH diaphorase staining was in fact produced by nNOS (T. M. Dawson *et al.*, 1991; Hope *et al.*, 1991). The mechanisms that lead nNOS neurons to preferentially survive in such profound neuronal loss in many neurologic disorders

are only now starting to be understood. Toxicity studies on primary cortical cultures from nNOS knockout mice have shown that such resistance is not due to nNOS itself (V. Dawson *et al.*, 1996). Although it is always feasible that alternative splice variants of nNOS are expressed at low levels and may provide some protection to nNOS neurons, this is unlikely. We hypothesize that nNOS neurons must possess unique protective mechanisms that render them resistant to the potentially toxic concentrations of NO they can produce.

In order to identify candidate proteins with a potential neuroprotective role, we performed serial analysis of gene expression (SAGE) in wild-type PC12 cells and in PC12 cells that had become resistant to NO toxicity (Gonzalez-Zulueta *et al.*, 1998). The first gene identified with the highest differential level of expression between the two cell populations was the manganese superoxide dismutase (MnSOD) gene. Knockdown of MnSOD levels by antisense oligonucleotides restored vulnerability to NO in the PC12 NO-resistant cells, whereas adenoviral overexpression of MnSOD conferred resistance to NO toxicity in wild-type PC12 cells (Gonzalez-Zulueta *et al.*, 1998). Inagaki and colleagues (Inagaki *et al.*, 1991) showed that MnSOD is localized in

somatostatin-containing neurons in the striatum, suggesting that nNOS neurons are enriched in MnSOD as somatostatin and nNOS are coexpressed in these neurons (V. L. Dawson *et al.*, 1991). We have shown that in primary cortical cultures MnSOD is enriched in nNOS neurons (Gonzalez-Zulueta *et al.*, 1998). Antisense knockdown and genetic knockout of MnSOD renders nNOS neurons susceptible to NMDA and NO toxicity, and overexpression of MnSOD via adenoviral vectors provides dramatic protection against NMDA and NO toxicity to cortical cultures (Gonzalez-Zulueta *et al.*, 1998). Our results indicated that MnSOD constitutes a major defense against excitotoxic and oxidative damage and appears to be essential for the resistance of nNOS neurons to NMDA and NO-induced neurotoxicity (Gonzalez-Zulueta *et al.*, 1998) (Fig. 3). MnSOD is one of the first cellular responses to oxidative stress and scavenges the highly reactive free radical superoxide anion. MnSOD in nNOS neurons may decrease the formation of peroxynitrite, rendering these neurons relatively resistant to the toxic actions of NO.

nNOS was shown to interact with phosphofructokinase-M (PFK-M) through the nNOS PDZ domain (Firestein and Bredt, 1999). In the brain, nNOS and PFK-M are both en-

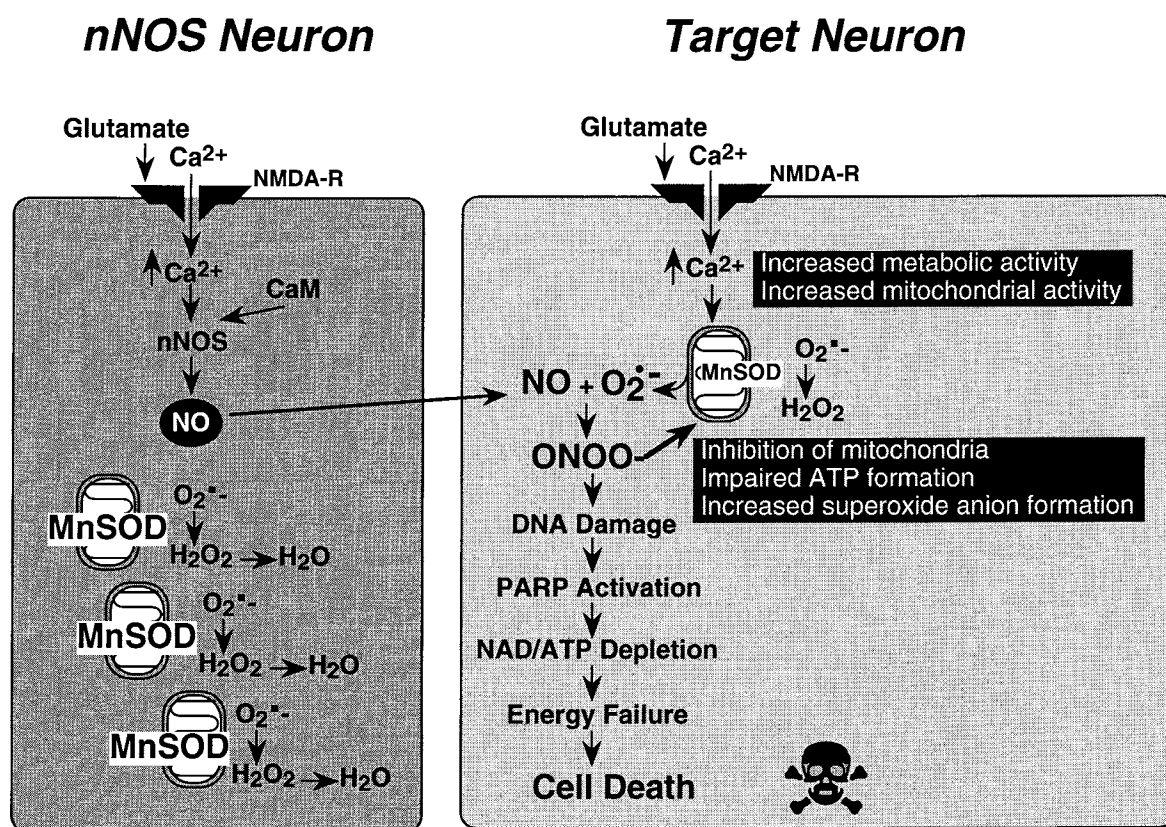

Figure 3 MnSOD protects nNOS neurons against NMDA and NO toxicity. MnSOD is highly expressed in nNOS neurons in comparison to adjacent neurons. NO generated in nNOS neurons does not have the opportunity to react with superoxide anion ($\text{O}_2^{\cdot-}$), as it is efficiently scavenged by MnSOD. NO readily diffuses to adjacent neurons where the low levels of MnSOD are not enough to scavenge the high concentrations of $\text{O}_2^{\cdot-}$ formed in the mitochondria following NMDA receptor stimulation by glutamate. In target neurons NO and $\text{O}_2^{\cdot-}$ react and generate high concentrations of peroxynitrite (ONOO^-). Peroxynitrite is a highly toxic oxidant that damages DNA and ultimately causes neuronal death.

riched in synaptosomes and, specifically, in the synaptic vesicle fraction, where they can interact. At the cellular level, PFK-M is enriched in neurons that express nNOS, and since fructose-1,6-bisphosphate, the product of PFK activity, is neuroprotective, interaction of nNOS and PFK may contribute to neuroprotection of nNOS-positive cells (Firestein and Bredt, 1999). Other putative protective mechanisms are also likely to exist in nNOS neurons.

Nitric Oxide in Neurologic Diseases

Role for Nitric Oxide in NMDA Receptor-Induced Excitotoxicity

The emergence of the hypothesis that excitotoxic injury is a major cause of neuronal death in the central nervous system in neurologic disorders is one of the most important developments in neuroscience (Meldrum and Garthwaite, 1990). A paradox that has come with the development of a better understanding of excitatory synaptic transmission is that excitatory neurotransmitters can also act as potent neurotoxins. Excessive release of excitatory amino acids is associated with convulsions and neurotoxicity (Moncada, 1993). Excitatory amino acids induce neurotoxicity via a three-stage process involving induction, amplification, and expression (Choi, 1992). Induction is due to overstimulation of glutamate receptors, which leads to increases in intracellular calcium, sodium, and chloride. Amplification occurs as a result of a further increase in cytoplasmic calcium concentration, which mediates the activation of enzymes such as protein kinase C, calmodulin-dependent enzymes such as nNOS, calpains, and phospholipases. Glutamate released from injured neurons can cause further glutamatergic receptor stimulation and the propagation of toxicity. Intracellular calcium overload can also activate catabolic enzymes such as proteases and endonucleases, leading to neuron degeneration. Excess glutamate acting via *N*-methyl-D-aspartate (NMDA) receptors mediates cell death in focal cerebral ischemia (Choi, 1988), trauma, and epilepsy, and it has been implicated in neurodegenerative diseases such as Huntington's disease and Alzheimer's disease (Meldrum and Garthwaite, 1990).

Since 1990, a major significant development in the study of excitotoxicity has been the demonstration that NO mediates a component of NMDA receptor-mediated neurotoxicity (V. L. Dawson *et al.*, 1991) (Fig. 4), and this advance paralleled the recognition and understanding of the important role played by NO in the central nervous system (Garthwaite and Boulton, 1995). The link between stimulation of NMDA receptors by glutamate and activation of nNOS was first demonstrated by Garthwaite and colleagues (Garthwaite *et al.*, 1988), and the first evidence for NO involvement in excitotoxicity was reported by V. L. Dawson and colleagues (1991). Our work in primary neuronal cultures showed that (1) NMDA-elicited neuronal death is prevented by NOS inhibitors or depletion of L-arginine from the culture me-

dium and (2) the NO donor sodium nitroprusside induces dose-dependent neuronal death that parallels the formation of cGMP. The addition of hemoglobin, which complexes with NO, prevents NMDA- and sodium nitroprusside-elicited neurotoxicity. These findings suggested that NO is involved in glutamate-mediated neuronal death, and they have been confirmed by several *in vitro* studies with NO inhibitors (Izumi *et al.*, 1992; V. L. Dawson *et al.*, 1993; Reif, 1993), and NO donor agents (Chen *et al.*, 1991; Lustig *et al.*, 1992; V. L. Dawson *et al.*, 1993). The inhibition of nNOS also protects against NMDA-induced lesions *in vivo* (Buisson *et al.*, 1992; Moncada *et al.*, 1992). Coexposure of primary cortical cultures to agents that decrease NOS catalytic activity, such as NMDA and arginine analogs, flavoprotein inhibitors, calmodulin antagonists, and calcineurin inhibitors, results in neuroprotection against NMDA toxicity. Compounds that release NO are neurotoxic and follow the same time course as NMDA neurotoxicity (V. L. Dawson *et al.*, 1991; Garthwaite and Boulton, 1995). Targeted disruption of the nNOS gene results in neuronal cultures that are resistant to NMDA toxicity, which indicates that nNOS neurons are the primary source of neurotoxic NO. Furthermore, cultures from nNOS null mice are markedly resistant to combined oxygen-glucose deprivation (V. Dawson *et al.*, 1996). These studies strongly suggest that NO plays a role in the mechanisms underlying NMDA-induced neuronal death.

The role of NO in NMDA-mediated neurotoxicity has been at times a controversial subject, owing to the publication of studies failing to demonstrate a role for NO in NMDA-induced toxicity in cortical cultures (Demerle-Pallardy *et al.*, 1991; Hewett *et al.*, 1993) or *in vivo* after a stroke (Buchan *et al.*, 1994). There are several experimental factors that appear to contribute to the variable detection of the NO component in NMDA excitotoxicity *in vitro*, including variable expression of NOS in neuronal cultures and the timing and intensity of the insult. Samdani *et al.* (1996) showed that the expression of nNOS is dependent on the culture paradigm, and that plating of neurons on glial feeder layers, which is a common practice, is associated with an impoverishment of nNOS-containing neurons and associated nNOS protein and catalytic activity. It is likely that the resistance of neurons in the cultures on feeder layers is due to the failure of the cultures to reach a mature phenotype. NMDA receptor-mediated NO-dependent neurotoxicity is developmentally regulated and may reach full expression in cultures only after a few weeks *in vitro*. Neurons plated on feeder layers show an immature phenotype with respect to nNOS expression in that total nNOS activity and number of nNOS-positive neurons is low (Samdani *et al.*, 1996). Also, serum-free medium prevents expression of nNOS at high enough levels to mediate toxicity. Furthermore, since nNOS is not expressed in cultured neurons grown on a polyornithine matrix until approximately 14 days *in vitro*, experiments performed before then will not yield any NO-mediated toxicity. Stribos *et al.* (1996) showed that the timing and exposure of cultured neurons to NMDA is crucial to the detection of a NO-dependent component of toxicity. It was shown that the NO component

Figure 4 Mechanisms of glutamate-induced oxidative stress and excitotoxicity. Activation of the NMDA receptor increases intracellular calcium (Ca^{2+}) levels. The depolarization activates voltage-sensitive calcium channels (VSCC), further increasing intracellular Ca^{2+} . Activation of kainate/AMPA receptors allows in some Ca^{2+} but mostly sodium (Na^{+}). Na^{+} depolarizes the cell, relieving the magnesium block of the NMDA receptor and increasing the activation of this receptor by glutamate. Activation of the metabotropic receptor releases inositol trisphosphate (IP_3) which raises intracellular Ca^{2+} levels from intracellular stores. Elevated intracellular Ca^{2+} levels activate nitric oxide synthase (NOS) to form NO, activate phospholipase A₂ (PLA₂) to initiate the arachidonic acid cascade which generates free radicals, and activate calpain, which converts xanthine to xanthine oxidase resulting in the generation of superoxide anion. NO produced at high levels reacts with O_2^- to generate high concentrations of peroxynitrite, which is a potent cellular toxin. Mitochondrial depolarization releases procaspase 2 and 9, apoptosis inducing factor, and cytochrome *c* to initiate apoptotic death cascades. Following depolarization, Na^{+} /K⁺-ATPase is activated to maintain membrane polarity. ATP is generated by the mitochondria through oxidative phosphorylation, which can also generate O_2^- through the loss of electrons from the electron transport chain to oxygen.

of NMDA toxicity diminished as duration of exposure to NMDA was extended longer than 5 min, suggesting the existence of NO-independent mechanisms of toxicity in cultures as well (Strijbos *et al.*, 1996).

The Role for Nitric Oxide in Ischemic Brain Injury

Glutamate has risen as a key mediator of ischemic brain injury (Choi and Rothman, 1990). Cerebral ischemia increases the extracellular concentrations of glutamate and aspartate, which stimulate the glutamatergic receptors and may lead to neuronal cell death if overstimulation occurs. Numerous studies indicate that the NMDA glutamate receptor mediates in large part neuronal damage following focal ischemia. The observation that NOS inhibitors at-

tenuate NMDA toxicity in neuronal cultures (V. L. Dawson *et al.*, 1991) and decrease brain damage produced by occlusion of the middle cerebral artery in mice (Nowicki *et al.*, 1991) provided strong initial evidence that NO plays a role in the pathways of cerebral ischemic injury. Elimination of the nNOS gene through transgenic technology results in primary neuronal cultures with significantly increased resistance to combined oxygen–glucose deprivation when compared to cultures from wild-type mice (V. Dawson *et al.*, 1996). Furthermore, exposure to the nonspecific NOS inhibitor L-NAME protects wild-type cultures from oxygen–glucose deprivation.

Tissue NO levels can be measured directly using a porphyrinic microsensor. Malinski and colleagues (1993) determined that after occlusion of the middle cerebral artery

(MCA), NO concentration in the ischemic area increases from nanomolar to micromolar levels within 20 min and then begins to decline owing to substrate depletion for NO synthesis. The initial peak of NO after the ischemic insult can be prevented by glutamate receptor antagonists. The increase in NO production correlates with an upregulation of nNOS gene transcription and catalytic activity, as well as with an increase in the number of nNOS neurons in the ischemic region (Z. G. Zhang *et al.*, 1994). After 60 min, nNOS activity returns to normal, and after 24 hours nNOS neurons are lost and nNOS activity decreases (Iadecola *et al.*, 1995a). Inhibition of nNOS with concentrations of NOS inhibitors that do not alter eNOS activity results in a reduction of infarct volume after MCA occlusion in rats and cats (Buisson *et al.*, 1992; Nishikawa *et al.*, 1994). In addition, the more selective nNOS inhibitor 7-nitroindazole, which effectively decreases nNOS activity but does not affect eNOS activity, is neuroprotective in models of cerebral ischemia (Yoshida *et al.*, 1994).

nNOS null mice have helped in the clarification of the role of nNOS in ischemic brain injury. These mice show reduced infarct size when compared with wild-type controls following permanent focal MCA occlusion (Huang *et al.*, 1994), as well as in a reperfusion model of transient MCA occlusion (Hara *et al.*, 1996). Furthermore, nNOS null mice show reduced hippocampal damage in a model of global cerebral ischemia (Panahian *et al.*, 1996). Interestingly, when nNOS null mice are treated with the nonselective NOS inhibitor nitro-L-arginine methyl ester, there are adverse effects on cerebral blood flow, and stroke volume is increased (Huang *et al.*, 1994).

In ischemic brain tissue, eNOS protein levels and catalytic activity also increase shortly after induction of ischemia (Z. G. Zhang *et al.*, 1993). If eNOS activity is diminished by high doses of NOS inhibitors, deleterious alterations of cerebral blood flow occur, and infarction volume is exacerbated. Consistent with this notion is the observation that MCA occlusion of eNOS null mice leads to larger infarcts in wild-type mice, and when eNOS null mice are treated with nonselective NOS inhibitors during MCA occlusion, infarct volume is reduced. Therefore, the currently available evidence suggests that the production of NO during cerebral ischemia has both deleterious and protective effects (Fig. 5), with neuronal NO playing an important role in mediating neuronal cell death and endothelial derived NO being neuroprotective by maintaining proper cerebral blood flow (Dalkara *et al.*, 1994).

iNOS protein and catalytic activity are also increased in the postischemic brain, but in contrast to nNOS and eNOS, iNOS expression does not occur until 6 to 12 hours after MCA occlusion (Iadecola *et al.*, 1995). In transient ischemia, iNOS is expressed in vascular cells, whereas in permanent ischemia, iNOS is primarily detected in neutrophils that infiltrate the ischemic area (Iadecola *et al.*, 1995). It is thought that the postischemic induction of iNOS expression leads to sustained generation of large amounts of NO, which subsequently causes delayed neuronal injury as indicated by the

reduction in infarct volume in iNOS null mice compared to wild-type mice following MCA occlusion (Iadecola *et al.*, 1997).

The Role of Nitric Oxide in Ischemic Preconditioning

Ischemic preconditioning is a well-known phenomenon in which sublethal ischemic insults induce robust protection against subsequent lethal ischemia in a variety of organ systems including brain, heart, liver, intestine, kidney, and lung (Kitagawa *et al.*, 1990; Ishida *et al.*, 1997). In the brain, ischemic preconditioning is mediated largely through the activation of NMDA glutamate receptors through increases in intracellular calcium (Kato *et al.*, 1992; Kasischke *et al.*, 1996). Because ischemic preconditioning induces such dramatic protection, understanding the early cellular events that account for the development of ischemic tolerance could lead to the development of novel therapeutic strategies for the treatment of patients at risk for a variety of neurologic disorders. Although ischemic preconditioning was first described in the 1980s (Murry *et al.*, 1986), the mechanisms underlying the powerful, protective effects of ischemic preconditioning remain uncertain. It appears as though activation of adenosine A1 receptors and K_{ATP} channels during the preconditioning ischemia appears to be important for the induction of tolerance (Heurteaux *et al.*, 1995). Mounting evidence indicates that NO may play a key role in the development of tolerance (Gidday *et al.*, 1999; Ping *et al.*, 1999). A potential clue linking the induction of ischemic tolerance to NO stems from our work showing that NO activates p21^{Ras} (Ras) (Yun *et al.*, 1998). Stimulation of NMDA receptors in cultured cortical neurons activates the Ras/extracellular signal activated kinase (Erk) pathway via calcium-dependent activation of nNOS and NO generation. This activation occurs through a non-cGMP-dependent mechanism and probably occurs through a redox-sensitive activation of Ras (Yun *et al.*, 1998). Our studies suggest that ischemic preconditioning induces Ras activation in an NMDA receptor- and NO-dependent, but cGMP-independent manner, and furthermore, we show that the Ras/Erk pathway is both necessary and sufficient for ischemic tolerance in neurons (Fig. 6).

Nitric Oxide in Parkinson's Disease

Parkinson's disease is a movement disorder characterized by the selective loss of dopamine neurons, particularly in the substantia nigra, that project to the striatum (Jenner *et al.*, 1992). It can be modeled in mice by injection of the toxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), which is metabolized to 1-methyl-4-phenylpyridium (MPP⁺) (Langston *et al.*, 1984; Heikkila *et al.*, 1989). MPP⁺ selectively targets dopaminergic neurons through the high-affinity dopamine reuptake transporter. MPP⁺ is a mitochondrial toxin, inhibiting mitochondrial complex I and causing a deficit in ATP production and an increase in superoxide anion formation in neurons (Kitayana *et al.*, 1992). The superoxide anion appears to play an important role in MPTP dopaminergic

Figure 5 Role of NO in ischemia-induced brain injury. NO is protective or destructive depending on the stage of evolution of the ischemic process and on the cellular source of NO. In the early stages following cerebral ischemia (<2 hours), the vascular actions of endothelial NOS (eNOS)-derived NO are beneficial by, mostly, promoting collateral circulation and microvascular flow. At the same time, glutamate-induced Ca^{2+} overload in ischemic neurons leads to activation of neuronal NOS (nNOS), resulting in production of NO. Large amounts of NO contribute to early neuronal death in the ischemic penumbra, a region in which glutamate excitotoxicity is most marked. At later times (>6 hours), inducible NOS (iNOS) expression is upregulated in astrocytes and in microglia, and large amounts of NO generated by this isoform contribute to late neuronal death and the progression of tissue damage.

toxicity, as mice overexpressing copper/zinc superoxide dismutase (SOD1) are significantly more resistant to MPTP-induced dopaminergic toxicity than their wild-type littermates (Przedborski *et al.*, 1992). Although the superoxide anion appears to play a prominent role in MPTP neurotoxicity, it has been suggested that the superoxide anion is poorly reactive and that it exerts many or most of its toxic effects through the generation of other reactive species (Halliwell *et al.*, 1992). Endogenous NO may react with superoxide to form peroxynitrite, which further inhibits mitochondrial function and damages DNA. DNA damage may lead to excessive activation of PARP in a cell with an already compromised ATP production capability. This pathway appears to play a prominent role in MPTP neurotoxicity, as selective inhibition of nNOS or deletion of nNOS attenuates, in a dose-dependent fashion, MPTP-induced striatal dopaminergic loss in mice (Przedborski *et al.*, 1996; Schulz *et al.*, 1995), and the selective inhibition of nNOS also protects against MPTP-induced dopaminergic neuronal cell death (Przedborski *et al.*, 1996). These protective effects were subsequently

demonstrated in a monkey model of MPTP-induced parkinsonism (Hantraye *et al.*, 1996).

Both neuronally derived NO and iNOS-derived NO from microglia may contribute to the loss of dopaminergic terminals and dopaminergic cell bodies, respectively (Liberatore *et al.*, 1999). Because nNOS is not localized within the vicinity of the substantia nigra dopamine-containing neurons, but is densely enriched within the striatum which is densely innervated by dopamine, it is likely that nNOS-derived NO contributes to terminal damage of dopaminergic neurons. Indeed, NO interaction with the superoxide anion to form peroxynitrite leads to the nitration of phenolic rings, particularly those of tyrosine contained within tyrosine hydroxylase (TH), the rate-limiting enzyme in dopamine synthesis. MPTP administration in mice leads to a time-dependent inactivation of TH by tyrosine nitration that appears to be mainly mediated through the actions of neuronally derived NO (Ara *et al.*, 1998). In contrast to the absence of nNOS within the substantia nigra, data suggest that iNOS is significantly upregulated within the substantia nigra following

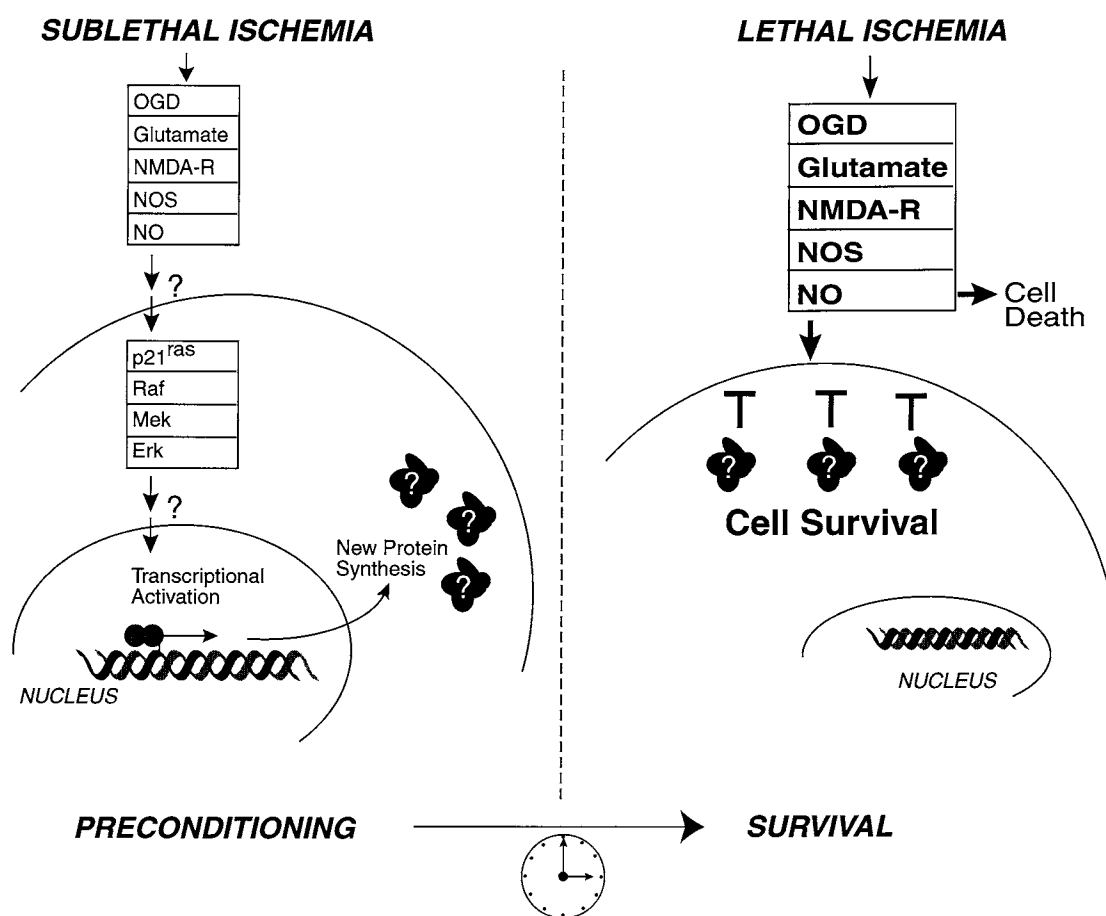

Figure 6 Model for NO/Ras/Erk signaling in ischemic preconditioning. Oxygen–glucose deprivation (OGD) or ischemia induces a multitude of cellular events that can result in preconditioning if the ischemic insult is brief, or in cell death if the insult is sustained. Cellular events triggered by a brief ischemic episode result in the reduction of the resting membrane potential of glia and neurons, leading to release of glutamate. Acting via NMDA receptors, glutamate induces a rapid elevation of intracellular calcium levels that activates a variety of signaling cascades, including activation of neuronal nitric oxide synthase (nNOS) and production of NO. NO leads to activation of p21^{ras}, which through the Raf–Mek–Erk signaling cascade can result in induction of gene transcription and new protein synthesis. Some of the newly made proteins may be neuroprotective and sufficient for cellular resistance to subsequent sustained ischemic insults that would normally be lethal for a naive neuron.

MPTP administration to mice. These changes precede or parallel MPTP-induced dopaminergic neuronal cell death, and mice lacking the gene for iNOS are significantly resistant to MPTP compared to wild-type littermates. Thus, iNOS appears to play a significant role in the death of dopaminergic neurons, whereas nNOS-derived NO appears to play a prominent role in the terminal damage and subsequent target-deprived dopaminergic cell death (Fig. 7).

Coupled with the emerging role of nNOS- and iNOS-derived NO in MPTP neurotoxicity is the identification of the downstream targets of NO- and MPTP-induced dopaminergic cell death. NO, superoxide anion, and peroxynitrite have vast potential targets, but they share at least one common downstream target in that they damage DNA (Burney *et al.*, 1998). DNA damage is a prime activator of PARP, which uses NAD as a substrate to transfer ADP-ribose groups to a variety of nuclear proteins. Activation of PARP appears to be critical in MPTP-induced dopaminergic cell death, as mice lacking the gene for PARP are dramatically

spared from MPTP neurotoxicity. Furthermore, MPTP potentially activates PARP exclusively in vulnerable dopamine-containing neurons of the substantia nigra, and MPTP elicits a novel pattern of poly-ADP-ribosylation of nuclear proteins that completely depends on neuronally derived NO. Thus, NO, DNA damage, and PARP activation appear to play a critical role in MPTP-induced parkinsonism (Mandir *et al.*, 1999).

Conclusion

The concepts of neuronal signaling have clearly been revolutionized by NO. The prominence of the interaction of NO with superoxide anion to form peroxynitrite as an important mediator of neuronal damage is also emerging. Elucidation of the downstream mediators of NO, superoxide, and peroxynitrite should contribute toward a better understanding of the neuronal messenger properties of NO versus its neuro-

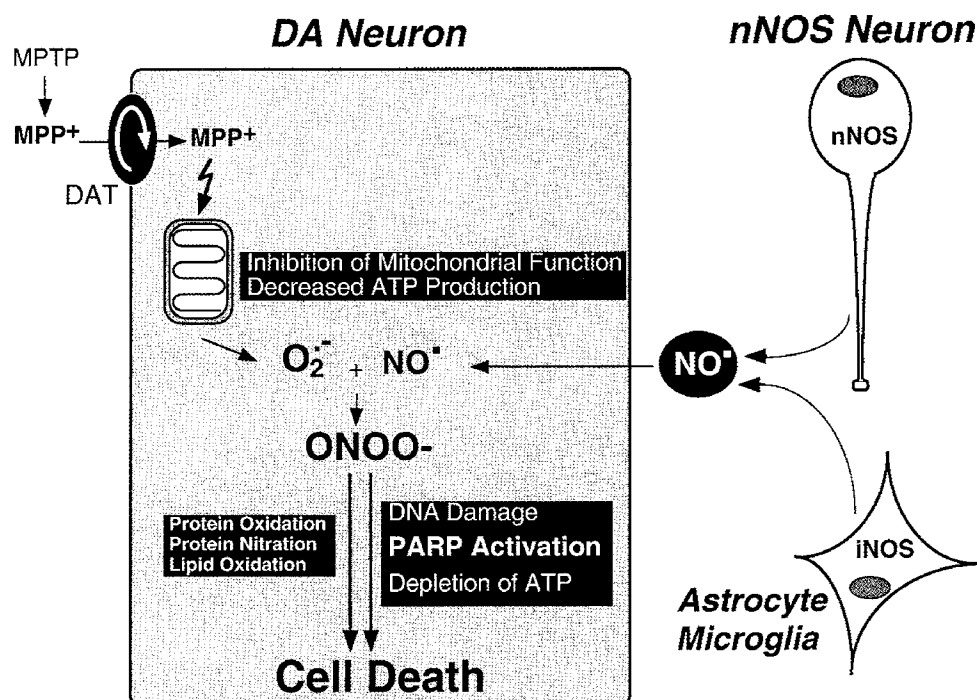

Figure 7 Model for MPTP-induced neurotoxicity. MPTP is converted to MPP⁺, which is selectively uptaken by dopamine (DA) neurons through the high-affinity DA transporter (DAT). MPP⁺ is a mitochondrial toxin that inhibits mitochondrial function, leading to decreased energy production and increased generation of superoxide ($O_2^{\cdot -}$). NO generated in neurons and astrocytes by neuronal NOS and inducible NOS, respectively, diffuses into DA neurons. NO reacts with $O_2^{\cdot -}$ to produce high concentrations of $ONOO^-$, a potent oxidant which injures cells by oxidizing proteins and lipids, nitrating proteins, and damaging DNA. DNA damage leads to PARP activation, energy depletion, and DA neuronal cell death.

toxic activities. Ultimately, it is hoped that knowledge of these processes will lead to the development of selective therapeutic agents that can be used to treat various neurological disorders.

Role of Macrophage-Derived Nitric Oxide in Target Cell Injury

Jorge E. Albina and Jonathan S. Reichner

Department of Surgery, Rhode Island Hospital, and Brown University School of Medicine, Providence, Rhode Island

MACROPHAGES CAN RECOGNIZE AND ELIMINATE TUMOR CELLS USING, FOR THIS PURPOSE, A VARIETY OF CYTOTOXIC EFFECTORS. ABUNDANT EVIDENCE SUPPORTS THE CONCEPT THAT NITRIC OXIDE (NO) IS ONE OF THESE CYTOTOXIC EFFECTORS, CAPABLE OF INDUCING APOPTOTIC DEATH IN A VARIETY OF NEOPLASTIC CELLS. JUST AS INTERESTING, HOWEVER, ARE MORE RECENT RESULTS THAT INDICATE NO CAN ACTUALLY SUPPRESS APOPTOSIS INITIATED BY EXPOSURE TO NO AND PROTECT CELLS FROM OTHER APOPTOSIS-INDUCING AGENTS. THIS CHAPTER, THEREFORE, WILL INITIALLY DISCUSS THE CHARACTERISTICS OF MACROPHAGE TUMOR CYTOTOXICITY AND THE POTENTIAL MECHANISMS BY WHICH NO CAN INDUCE APOPTOSIS IN TUMOR CELLS. IN ADDITION, OBSERVATIONS OF SPONTANEOUS AND ACQUIRED RESISTANCE TO NO WILL BE ANALYZED. LAST, THE RELEVANCE OF RESULTS OBTAINED USING ANIMAL CELLS TO THE BIOLOGY OF THE HUMAN MACROPHAGE WILL BE CONSIDERED.

Introduction

The nonspecific stimulation of macrophages by intracellular bacteria determines the development of host resistance to the proliferation of neoplastic cells that is not mediated by specific antibodies or by classic, cell-mediated immune responses (Jun *et al.*, 1996; Hibbs *et al.*, 1990). In this regard, the experimental induction of chronic protozoan infections in AKR mice was shown to delay the onset of spontaneous leukemia in the animals (Aliprantis *et al.*, 1996). Subsequent work identified the activated macrophage as the mediator of this acquired and nonspecific antitumor activity (Brüne *et al.*, 1996; MacMicking *et al.*, 1997; Hirokawa *et al.*, 1994). Peritoneal macrophages obtained from mice chronically infected with unrelated pathogens such as protozoa or intracellular bacteria were shown to be cytotoxic for syngeneic, allogeneic, and xenogeneic tumor cells *in vitro*. Moreover, macrophages mobilized to sites of infection were found to undergo the functional and morphological modifications characteristic of the activated state and to acquire the capacity to

recognize and destroy neoplastic cells (Clark *et al.*, 1997). The presence of an ongoing local cell-mediated immune response was shown to be necessary to induce macrophage activation, endowing the cell with tumoricidal capacity (Aliprantis *et al.*, 1996). The paradigm of a two-stepped sequence of macrophage priming and activation for tumoricidal activity evolved from investigations which revealed that activation *in vitro* required the presence of interferon- γ (IFN- γ), a T-lymphocyte-derived cytokine, and bacterial products such as lipopolysaccharide (LPS) or muramyl dipeptide as second signals (Adams and Hamilton, 1984; Cohn, 1978).

Tumor cell lysis and cytostasis have been shown to be accomplished through an arsenal of effector mechanisms elaborated by the activated macrophage. These cytotoxic effectors include various proteases, reactive oxygen intermediates, tumor necrosis factor α (TNF- γ), and reactive nitrogen species (Adams *et al.*, 1982; Adams and Nathan, 1983). Central to this chapter will be evidence regarding the participation of NO or its more reactive derivatives in macrophage-dependent tumor cell cytotoxicity and, more

narrowly, that which characterizes NO-mediated tumor cell death as apoptotic in mechanism (Cavalli *et al.*, 1994; Tsang *et al.*, 1993).

Role of Macrophage-Derived NO as an Antitumor Effector

Activated murine macrophages induced cytostasis in tumor cell lines only when the culture medium contained L-arginine (Hibbs *et al.*, 1987a, b). This antitumor effect correlated with the metabolism of L-arginine to NO_2^- and L-citrulline, as inhibition of this pathway by the L-arginine analog N^G -monomethyl-L-arginine (N-MMA) suppressed cytostasis. Moreover, cytostasis was accompanied by the inhibition of aconitase, an enzyme in the citric acid cycle. NO was subsequently shown to be the precursor for NO_2^- and NO_3^- produced by macrophages from L-arginine, and authentic NO gas duplicated the cytostatic injury (Drapier *et al.*, 1988; Hibbs *et al.*, 1988; Stuehr and Nathan, 1989). Previous reports had shown that tumor cells cocultured with activated macrophages had reduced mitochondrial respiration and that macrophages could not lyse L1210 leukemia cells when cultured in the presence of excess glucose (Hibbs *et al.*, 1988, 1987b). Although NO inhibited mitochondrial oxidative phosphorylation, a compensatory increased reliance on glycolysis to generate ATP by tumor cells injured by NO seemed to explain these findings. Indeed, the oxidoreductases of electron transport chain complexes I and II were specifically inhibited by the activated macrophages, whereas other more distal enzymes of the electron transport chain were thought to be unaffected (Hamilton *et al.*, 1996). A common mechanistic explanation for these diverse findings emerged when iron loss was identified as a component of the metabolic damage of tumor cells caused by activated macrophages (Drapier and Hibbs, 1988; Hibbs *et al.*, 1984). All enzymes initially shown to be inhibited in tumor cells exposed to macrophages contain nonheme iron-sulfur clusters. The degradation of these clusters through iron sequestration by NO into iron-nitrosyl complexes results in loss of enzyme activity. Exposure of tumor cells to authentic NO gas was able to mimic the L-arginine-dependent antitumor effects of activated macrophages, including loss of intracellular iron as well as inhibition of mitochondrial respiration, aconitase, and DNA synthesis (Hibbs *et al.*, 1988; Stuehr and Nathan, 1989). The provision of excess iron to these cells restored enzyme activity and prevented tumor cell death. Since none of the enzymes in the glycolytic pathway contain iron-sulfur centers, glycolysis remains functional as an ATP-generating system in the presence of NO (Albina and Mastrofrancesco, 1993).

The observed suppression of DNA synthesis in tumor cells injured by cytotoxic macrophages could be explained by the NO-dependent inhibition of ribonucleotide reductase, a rate-limiting enzyme in DNA synthesis (Soo Kwon *et al.*, 1991; Lepoivre *et al.*, 1992; Kwon *et al.*, 1991). Further

contributions by Hibbs and co-workers and other investigators led to the conclusion that NO is a mediator of the cytotoxic activity of activated macrophages and to the proposal that NO kills or limits growth in tumor cells by inducing metabolic failure and inhibiting DNA replication through the perturbation of key enzymes via iron sequestration. The profound inhibition of protein synthesis that is also found in cells exposed to NO was more recently explained by the NO-dependent phosphorylation of the initiation factor eIF-2 α and the inhibition of the 80S ribosomal complex formation (Kim *et al.*, 1998).

Since the aforementioned seminal publications, a better understanding of the complexity of NO synthesis and chemistry has mandated the reconsideration of the potential mechanisms of NO-dependent cellular injury. NO production is now recognized as resulting from the five-electron oxidation of one of the chemically equivalent guanidino nitrogens of L-arginine through the action of nitric oxide synthase (NOS) (reviewed in Morris and Billiar, 1994). Two basic isoforms of NOS have been described to date based on their constitutive (cNOS) or inducible (iNOS) expression. The inducible form of NOS can be found in several cell types including macrophages, hepatocytes, fibroblasts, endothelial cells, and vascular smooth muscle cells following stimulation with a variety of factors including microbes, microbial products, and inflammatory cytokines. Expression of iNOS is often increased synergistically by combining several of these agents.

Mentioned earlier was the intricacy of NO chemistry. Indeed, NO per se has been shown to behave rather poorly as a free radical. It is its reactivity with molecular oxygen, transition metals, and superoxide that results in the formation of compounds with potentially profound cytotoxic effects. These derivatives of NO include highly reactive intermediates such as its oxidation product nitrosonium ion (NO^+), its reduction product nitroxyl radical (NO^\cdot), the product of its reaction with superoxide anion, peroxynitrite (ONOO^-), as well as other compounds generated from these precursors (Cavalli *et al.*, 1994; Tsang *et al.*, 1993; Muijsers *et al.*, 1997). In reacting with dioxygen, NO forms *N*-nitrosamines, and the nitrosation of thiols results in the generation of *S*-nitrosothiols. The nitrosation of amines and the deamination of DNA bases could, as will be discussed later, contribute to the toxicity of NO (Nguyen *et al.*, 1992; Sonoki *et al.*, 1997).

The inhibition of iron-sulfur cluster-containing enzymes by NO has already been mentioned. Disruption of nonheme iron enzymes by NO, including aconitase, NADH:ubiquinone oxidoreductase, succinate:ubiquinone oxidoreductase, and cytochrome oxidase, explains some of the most prominent metabolic consequences of cellular exposure to NO (Hibbs *et al.*, 1990). Interestingly, NO can also lead to cellular zinc depletion (Berendji *et al.*, 1997) with metal ion loss from zinc-containing proteins, as shown for metallothionein, and destruction of Cys-type zinc fingers, an effect that will potentially alter transcription factor binding to DNA (Kröncke *et al.*, 1994).

The reactivity of NO with superoxide anion and the resulting formation of peroxynitrite have received considerable attention (Muijsers *et al.*, 1997). Beckman and others have contended that most biological effects of NO thought to mediate cytotoxicity, including mitochondrial inhibition, suppression of ribonucleotide reductase, deamination of DNA, and direct induction of apoptosis, can be attributed to ONOO⁻ (Beckman and Koppenol, 1996; Lin *et al.*, 1995). Moreover, ONOO⁻ nitrosylates protein-bound tyrosine residues. Such modification can have profound functional significance. It has been shown, for example, that nitrosylation inhibits tyrosine phosphorylation, an effect with potentially important consequences in signal transduction (Schäffer *et al.*, 1997). Nitration of cytoskeletal proteins, in turn, may target them for proteolysis or fundamentally alter their structure and function.

Because of the limited stability and diffusion range of ONOO⁻, it is unlikely that this compound is the direct effector molecule released by macrophages (Saran and Bors, 1994). It is conceivable that NO released from the activated macrophages reacts with superoxide within the target cell to generate ONOO⁻. Because superoxide anion is mainly produced at the electron transport chain in cells lacking NADPH oxidase activity, and considering that NO has been shown to increase the release of superoxide by mitochondria (Poderoso *et al.*, 1996, 1998), the site of intracellular ONOO⁻ formation could be at or in close proximity to mitochondria, subcellular organelles thought to have a central role in the development of apoptosis.

NO-mediated cytotoxicity may also occur as a result of a chemical interaction with hydrogen peroxide (H₂O₂). In the presence of catalytic levels of a trace metal (perhaps intracellular iron liberated from iron-containing prosthetic groups by NO), a potent cytotoxic oxidizing species can be generated from a chemical reaction involving NO and H₂O₂ (Farias-Eisner *et al.*, 1996). Two inferences may be drawn by the existence of such a pathway regarding mechanisms of cellular sensitivity or resistance to NO toxicity. First, because NO inhibits catalase, the relative sensitivity of a target cell to this NO/H₂O₂/metal cytotoxic mechanism will depend on the activity of the glutathione peroxidase–glutathione reductase system to degrade H₂O₂. Second, this mechanism predicts that increased H₂O₂ formed by the action of superoxide dismutase may accentuate, rather than protect from, oxidative damage.

More recently, another potential mechanism by which NO may cause tumor cell cytostasis was reported (Buga *et al.*, 1998). NO caused a potent (1–10 μ M) inhibition of growth of Caco-2 human colon carcinoma cells by mechanisms attributed to S-nitrosylation and inhibition of ornithine decarboxylase. Moreover, N^G-hydroxy-L-arginine, the precursor to NO in the NO synthase-catalyzed conversion of L-arginine to NO plus citrulline, also inhibited tumor cell growth, but by inhibiting the catalytic activity of arginase. Both of these cytostatic effects were independent of any action of cyclic GMP (Buga *et al.*, 1998). The observations that N^G-hydroxy-L-arginine and NO inhibit sequential steps

in the arginine–polyamine pathway provide yet another possible mechanism by which elevated NO synthase activity could lead to tumor cell cytostasis.

It follows from the preceding paragraphs that, although the cytotoxicity of NO or its derivatives and the identification of their cellular targets are growing, the adjudication of specific mediators for the toxic effects of NO remains in flux.

Recent results have added another level of complexity to the understanding of the specific role of NO in determining macrophage-dependent cytotoxicity. In this regard, macrophages isolated from experimental wounds in rats are capable of producing NO just as activated peritoneal macrophages (Mateo *et al.*, 1996). In contrast to the peritoneal macrophages, however, the wound-derived cells are not cytotoxic toward NO-sensitive P815 cells. Moreover, macrophages from knockout mice for the NFIL-6 (C/EBP β) transcription factor produce NO in quantities similar to those from wild-type mice but, like wound-derived cells, are incapable of killing P815 targets (Tanaka *et al.*, 1995). Whether, as it appears, NO is necessary but not sufficient to explain NO-dependent cytotoxicity is under current investigation.

Autotoxicity of NO: Induction of Macrophage Apoptosis by Endogenous or Exogenous NO

Although an important role for macrophage-derived NO as an antineoplastic effector molecule has been established at least *in vitro*, it is also true that the generation of NO exerts significant negative effects on the macrophage that produces it. Work from our laboratory indicated that phagocytosis and the production of reactive oxygen intermediates are profoundly suppressed in rat resident or *Corynebacterium parvum*-elicited peritoneal macrophages cultured in conditions allowing NO production (Albina *et al.*, 1989, 1990). Moreover, NO-producing macrophages exhibit reduced electron transport chain activity, enhanced reliance on glycolysis for energy generation, a reduced ATP content, and decreased protein synthesis. These metabolic alterations are similar to the effects of NO on tumor cells.

In an additional observation, macrophages activated with IFN- γ and LPS rapidly lose their L-arginine-dependent cytotoxic capacity when cultured in media containing L-arginine, and this loss of tumoricidal activity correlates with macrophage death (Albina *et al.*, 1989; Takema *et al.*, 1991). Investigation of the mechanism of macrophage death associated with the production of NO revealed, through morphologic and molecular means, that death in these cells exhibits the characteristics of apoptosis (Albina *et al.*, 1993). Apoptosis, or programmed cell death, is an active process of cell self-destruction with distinct morphologic and molecular characteristics. Morphologically, cells undergoing apoptosis demonstrate prominent cytoplasmic and nuclear condensation, with progressive formation of cell surface blebs and shedding of membrane-bound apoptotic bodies. At the molecular level, DNA is fragmented by a specific Ca²⁺,

Mg²⁺-dependent endonuclease into oligonucleotides 180 to 200 base pairs in length. Necrosis, in contrast, is a passive and unregulated result of cell death caused by catastrophic toxic or traumatic events. Necrotic cells exhibit organelle swelling and early dissolution of the plasma membrane. DNA in necrotic cells is degraded in a random fashion and appears in gel electrophoresis analysis as a smear without the distinct banding or laddering characteristically found in apoptotic cells.

Macrophages expressing iNOS or exposed to NO gas show cytoplasmic and nuclear condensation, as well as the internucleosomal DNA fragmentation diagnostic of apoptosis (Albina *et al.*, 1993). The role of NO in determining apoptotic death was confirmed by the protective effects of culture in L-arginine-deficient media or the inclusion of inhibitors of NOS in the cultures (Albina *et al.*, 1993). Thus, the production of NO by activated macrophages leads to their functional suppression and, ultimately, to their apoptotic death.

The diagnosis of cell death through apoptosis was originally based on morphologic changes including chromatin condensation, cell blebbing, apoptotic body formation, cell detachment, and the lack of a prominent inflammatory response (Möröy and Zörnig, 1996; Gerschenson and Rotello, 1992). Following the classic studies of Wyllie (Harbrecht *et al.*, 1997) indicating the disruption of DNA during apoptosis by specific nucleases, more recent work has relied on the detection of more or less specific patterns of DNA fragmentation through electrophoretic, isotopic, or enzymatic means for the molecular diagnosis of apoptosis. It has been shown, however, that DNA fragmentation is a dispensable feature of apoptosis and that morphologic evidence for apoptotic death can be found in circumstances where DNA damage is not detectable (Rubin *et al.*, 1989; Bortner *et al.*, 1995; Cohen *et al.*, 1992). Indeed, the relevance of nuclear changes in apoptosis has been ingeniously challenged by the demonstration of clear-cut apoptotic morphology in the absence of a cell nucleus (Jacobson *et al.*, 1994). Moreover, although the original paradigm of programmed cell death indicated a requirement for *de novo* protein synthesis, that is, the engagement of a protein-based death machinery in cells undergoing apoptosis, this also has been shown to be a nonessential component of the apoptotic process, and, indeed, protein synthesis inhibition can initiate apoptosis in certain cells.

The preceding paragraph highlights some of the difficulties encountered when reviewing existing information on the role of specific mediators, in this case NO, in determining apoptosis. Whereas morphologic and molecular evidence should ideally be brought together to confirm the diagnosis of apoptosis, this is not always the case. In the body of literature pertaining to the induction of apoptosis by NO, seldom is morphologic characterization employed for diagnosis. Most published data rely on some or other determination of DNA damage in the cells. Whether this is sufficient to diagnose apoptotic death to the exclusion of necrotic death is questionable. In our own work, we have found that cell ex-

posure to certain doses of H₂O₂ or NO results in simultaneous DNA fragmentation and cell membrane failure, the first a putative measure of apoptosis, the second, of necrosis. In short, documentation of DNA damage, even if meeting the criteria thought to be pathognomonic of apoptosis, does not appear to rule out necrotic cell death. With this caveat in mind, then, we review existing evidence on the causation and mechanisms of NO-dependent tumor cell apoptosis.

Mechanisms for NO-Dependent Apoptosis

Given the gaseous, cell-permeant nature of NO and in view of the multiple potential molecular targets for NO in living cells, it is not surprising that the intimate mechanism for NO-dependent apoptosis is not yet known. By the same token, mechanisms by which cells can escape its toxic effects are difficult to envision. Results from our laboratory demonstrated that activated macrophages induce apoptotic death in some tumor cells (i.e., P815, RAW 264.7) using NO as the cytotoxic effector, that intimate cell contact is not necessary for induction of apoptosis, and that authentic NO gas or NO derived from chemical donor agents could substitute for macrophages in inducing apoptosis (Cui *et al.*, 1994). In contrast, L929 tumor cells were refractory to NO-mediated effects regardless of whether NO was derived from activated macrophages, authentic gas, or chemical donors, even when delivered at high concentrations and for prolonged periods. These cells were killed, incidentally, by either macrophage-derived or recombinant TNF- α through an apoptotic pathway. Reports by others have highlighted the relative NO resistance of other cell types, including hepatocytes (Nussler and Billiar, 1993; Schwarz *et al.*, 1995) and rat mesangial cells (Brüne *et al.*, 1996). By exploiting the insensitivity of certain tumor cells to NO, certain speculative considerations can be made regarding the pathways to apoptotic death.

Impact of NO on Oxidative Metabolism

As mentioned before, early descriptions of the effects of NO on tumor cells and on macrophages indicated the suppression of oxidative metabolism through the inhibition of aconitase and the electron transport chain as causal alterations in the induction of cell death. A reduced oxidative capacity mandates the enhanced generation of metabolic energy through glycolysis. Indeed, the macrophage, a prototypically glycolytic cell, responds to iNOS expression with increased glucose uptake and metabolism through glycolysis and the hexose monophosphate shunt, as if to compensate for a diminished energy production through oxidative metabolism (Albina and Mastrofrancesco, 1993b). In apparent contradiction to these observations, it was demonstrated (Häussinger, 1983; Vedia *et al.*, 1992) that the glycolytic enzyme glyceraldehyde-3-phosphate dehydrogenase (GAPDH) can be inhibited by nitric oxide. However, and probably be-

cause of the large GAPDH protein content found in most cells, the flux of glucose carbon through GAPDH is unimpeded in peritoneal macrophages even when this enzyme is significantly suppressed by NO (Mateo *et al.*, 1995). It is not until GAPDH is almost fully inhibited that lactate production is diminished. It appears that complete suppression of GAPDH constitutes a terminal event, since cell viability is compromised at that time (Albina and Reichner, 1995).

Although the construct of NO-dependent metabolic suppression as a mechanism for apoptosis is attractive and supported by the observed increased reliance on glycolysis of NO-injured cells, other results tend to reduce its apparent causative importance. In this regard, NO-mediated inhibition of key iron-sulfur cluster enzymes is thought to be determined by iron sequestration and loss. Experiments comparing NO-sensitive RAW 264.7 cells to NO-resistant L929 cells demonstrated identical rates of iron loss on exposure to the NO donor agent *S*-nitroso-*N*-acetylpenicillamine (SNAP) (Albina and Reichner, 1998). Additionally, culture of either cell type with SNAP was followed by similar and moderate suppression of mitochondrial respiration. However, whereas RAW 264.7 cells readily underwent apoptosis, L929 cells maintained viability even at the highest concentrations of SNAP. These findings suggest that the classic paradigm holding NO cytotoxicity as mediated through metabolic inhibition may not be fully explanatory.

Role of Antioxidant Species

The free radical nature of NO and its derivatives allows the hypothesis that NO induces apoptosis through mechanisms common to those used by reactive oxygen intermediates. When speculating on potential mechanisms of NO sensitivity or resistance of different cell types, one should consider that the cellular content of antioxidant systems may be involved in determining the sensitivity or resistance to NO-dependent apoptosis (Walker *et al.*, 1995). Cells characterized by a high antioxidant content resist NO and lose such resistance when depleted of glutathione (GSH), yet the role of this antioxidant in cell death or survival remains unclear. Since NO or its by-products can *S*-nitrosylate GSH, and because *S*-nitroso-GSH (GSNO) can, in turn, release NO, the possibilities exist for GSH to serve as a NO trap and/or as a NO transporter and subsequent donor (Wink *et al.*, 1994). Indeed, because GSH can react with peroxynitrite and with intermediates of the reaction of NO with molecular oxygen, it has been proposed that formation of GSNO can serve to detoxify reactive nitrogen species (Wink *et al.*, 1994). In vascular smooth muscle cells exogenous or endogenous NO induced apoptosis in the context of markedly reduced intracellular GSH content (Zhao *et al.*, 1997). Addition of a cell-permeant form of GSH restored its intracellular concentration and prevented apoptosis. The protective effects of the GSH precursor *N*-acetylcysteine (NAC) have been reported, and the depletion of GSH resulted in higher toxicity of NO in V79 fibroblasts (Chesrown *et al.*, 1994). In

contrast, cells derived from the chronic exposure of RAW 264.7 to IFN- γ and endotoxin, which are resistant to endogenously generated NO, were found to contain less GSH than the parental, NO-sensitive RAW 264.7 cells (Boggs *et al.*, 1998). If GSH was, in turn, depleted from the parental cells, these became resistant to the effects of a NO donor agent. The authors proposed that a high intracellular GSH content would serve to reverse the inactivating *S*-nitrosylation of caspases by NO and allow for the apoptotic process to proceed (see later). Interestingly, a decreased intracellular GSH concentration has been shown to correlate with enhanced toxicity of a variety of agents and to be associated with a change in the type of cell death from apoptosis to necrosis (Shimizu *et al.*, 1994). Moreover, whereas GSH, NAC, and ascorbic acid prevented the apoptotic effects of NO, they augmented those of a nitrosonium ion donor (Khan *et al.*, 1997).

Our experimental data do not support a role for NO-dependent oxidative injury as a mechanism for tumor cell apoptosis. NO-dependent apoptosis of sensitive cell lines (P815, RAW 264.7) was not prevented by antioxidants or radical scavengers including DMSO (1–100 mM), ethanol (1–100 mM), mannitol (1–100 mM), thiourea (1–10 mM), or uric acid (1–5 mM), nor was it exaggerated by the addition of menadione (0–200 μ M), an intracellular superoxide generator. A protective effect against NO-dependent apoptosis was found, however, when NAC was added to cultures (J. E. Albina and J. S. Reichner, 1998, unpublished observations). NAC can act as a direct extracellular antioxidant, or it can be incorporated into cells and support the production of GSH (Stuehr and Nathan, 1989). It has been shown, in this connection, that the affinity of NO for sulfur groups in GSH is $>10^6$ -fold higher than that for nucleic acid bases. As mentioned earlier, then, GSH could act as an intracellular “sink” for NO and neutralize some of its toxic effects. However, others have shown that the antiapoptotic effects of NAC are not explained by changes in intracellular GSH content (Jones *et al.*, 1995). In particular connection to its effects on NO-dependent cytotoxicity, NAC (and other thiols) can theoretically alter the kinetics of NO release from the NO donor agent used in our experiment, SNAP (Huot *et al.*, 1995). As thiols have been proposed to accelerate the rate of NO release from donors, it may be possible that NAC (and/or other thiols) act by provoking the explosive release of NO from SNAP, thus shortening its presence in the cultures. It is not clear whether it is the maximal NO concentration reached in culture, the duration of NO exposure, or the product of these two factors that is essential in determining NO-mediated apoptosis. Evidence has been provided indicating that it is the total exposure to NO, as defined by integrated concentration–time curves, that correlates best with the induction of apoptosis (Messmer and Brüne, 1996a).

NO and the Induction of Direct DNA Damage

It is also possible that NO may induce apoptosis through direct DNA damage, as NO can deaminate purine and pyrim-

idine bases in DNA and result in increased strand breaks and mutagenesis (Nguyen *et al.*, 1992; deRojas-Walker *et al.*, 1995). Moreover, exposure of isolated nuclei to NO donor agents is followed by DNA strand breaks (Schwarz *et al.*, 1995). Therefore, the process of apoptosis could be initiated directly as a result of DNA damage and may occur in addition to, or independently from, the metabolic effects of NO. In this regard, a mechanism of energetic failure and cell death invokes the activation of poly(ADP-ribose) polymerase (PARP) by DNA damage (Heller *et al.*, 1995; Zhang *et al.*, 1994). PARP is a nuclear enzyme that binds to and is activated by DNA strand breaks (Berger, 1985). Overactivation of PARP would lead to the rapid consumption of its substrate, NAD⁺, and through NAD⁺ depletion to the inhibition of glycolysis and a catastrophic decrease in the ATP content of the cells (Schraufstatter *et al.*, 1986). Evidence for PARP activation and for its correlation with cell death following H₂O₂ injury has been presented (Schraufstatter *et al.*, 1986).

In regard to a role for PARP in NO-mediated cytotoxicity, a mutant cell line with inactive PARP was shown to undergo DNA damage on exposure to low concentrations (<0.6 mM) of the NO donor agent sodium nitroprusside (SNP), just like its wild-type counterpart, but not to undergo lysis (Heller *et al.*, 1995). Higher concentrations of SNP elicited cell lysis in wild-type and mutant cells alike, indicating other, PARP-independent mechanisms of NO toxicity. Consistent with a PARP-independent pathway are the findings that the PARP inhibitors nicotinamide and 3-aminobenzamide failed to protect RAW 264.7 or P815 cells from NO release from SNAP, and that PARP can be cleaved and inactivated in the process of NO-mediated RAW 264.7 apoptosis (Yamazaki and Birnboim, 1995) (see later). This observation appears particularly germane because PARP inhibition in thymocytes increases the number of DNA strand breaks and actually induces apoptosis. Indeed, in our own work, high concentrations of the PARP inhibitors mentioned earlier dramatically increased spontaneous DNA fragmentation in RAW 264.7 cells. Thus, the evidence for the direct involvement of PARP activation or inhibition in mediating NO-dependent apoptosis remains controversial.

NO and Direct Mitochondrial Injury

In connection with the role of mitochondria in NO-mediated apoptosis, NO induces permeability transition in isolated mitochondria, resulting in the release of factors capable of triggering apoptotic changes in isolated cell nuclei (Hortelano *et al.*, 1997). Moreover, exposure of thymocytes to NO determined the disruption of the mitochondrial membrane potential, increased generation of reactive oxygen species and exposure of phosphatidylserine on the outer plasma membrane, and increased apoptotic nuclear changes. Most importantly, chemical prevention of the mitochondrial permeability transition prevented NO-mediated apoptosis of the cells (Hortelano *et al.*, 1997).

NO Resistance: NO as a Positive and Negative Regulator of Apoptosis

Work from our laboratory mentioned previously identified some cell types as particularly resistant to the apoptotic effects of NO. In other experimental models it has been shown that NO resistance can be acquired by a variety of cell types. In this connection, Kim *et al.* (1995) reported that pre-exposure of rat hepatocytes to low concentrations of the NO donor agent SNAP offered protection to a second exposure to higher concentrations of this compound, that protein synthesis was required for expression of acquired resistance, and that the protective effect could be mediated through the upregulation of ferritin levels or the induction of heme oxygenase. Favoring the oxidant hypothesis of NO toxicity, they also reported that SNAP pretreatment resulted in cross-protection against H₂O₂.

Metallothionein overexpression induced by zinc chloride also afforded some protection against NO in NIH 3T3 cells (Schwarz *et al.*, 1995). Experiments in our laboratory also used zinc salts to prevent SNAP-induced apoptosis. Indeed, zinc salts were, in our hands, the most potent tested inhibitors of SNAP-induced apoptosis. The inclusion of zinc in our experiments, and in those by others, was predicated on its reported inhibitory effects on the endonucleases thought to mediate DNA fragmentation (Messmer *et al.*, 1995; Lin *et al.*, 1997). Additional mechanisms by which NO can protect cells from apoptotic death have been reported, including the heat-shock induction of protein 70 (HSP70) (Müller *et al.*, 1997), heme oxygenase 1 (Ceneviva *et al.*, 1998), and cyclooxygenase 2 (von Knethen and Brüne, 1997).

Acquired resistance to NO was also documented in studies where RAW 264.7 cells were exposed to low-dose *S*-nitrosoglutathione (25–200 μ M) or pretreated with IFN- γ and LPS in the presence of a NOS inhibitor prior to culture with an otherwise lethal concentration of *S*-nitrosoglutathione (1 mM) (Brüne *et al.*, 1996). Pretreatment with the NO donor agent or with the cytokine–LPS–NOS inhibitor combination prevented apoptotic death and was associated with a substantial decrease in p53 accumulation (Brüne *et al.*, 1996).

In a similar manner, Genaro *et al.* (1995) reported that murine B cells exposed to NO or to NO donor agents in low concentrations avoided spontaneous apoptosis, that treatment prevented the natural decay in cellular bcl-2 levels, and, most interestingly, that the protective effects of NO could be duplicated by cell-permeant analogs of cGMP. The latter observation is particularly interesting because it connects apoptosis with one of the earliest recognized effects of NO, namely, the activation of guanylate cyclase. It has been contested in the literature, however, by work demonstrating a lack of effect of cGMP analogs in preventing NO-mediated apoptosis in RAW 264.7 cells (Messmer *et al.*, 1995).

Just mentioned was the potential involvement of pro- and antiapoptotic molecules in determining cell resistance or sensitivity to NO. In this regard, the signal transduction and gene expression events leading to apoptosis remain incom-

pletely defined (Stewart, 1994). The concept that apoptosis results from the activation of a death gene(s) stemmed from observations that cycloheximide or actinomycin D could prevent apoptosis in some circumstances. As mentioned earlier, this model was challenged by findings of apoptosis following treatment with inhibitors of protein or RNA synthesis. A release mechanism through which these inhibitors allow the expression of a gene or genes that mediate apoptosis was proposed to explain cases of inhibitor-induced apoptosis. There are, however, instances where apoptosis is not influenced one way or another by inhibitors of protein or RNA synthesis.

This confusing picture recurs where specific signal transduction pathways and transcription factor physiology have been studied in relation to the development of apoptosis. The apparent similarities between NO- and H₂O₂-mediated responses may offer some guidance to begin to clarify this issue. It was originally proposed that H₂O₂-mediated cellular events, including apoptosis, were initiated by DNA damage. More recent evidence, however, has indicated that H₂O₂ is capable of altering cell membranes through lipid peroxidation and is capable of initiating signaling at the membrane through tyrosine kinases, ion channels, and G proteins, and that downstream activation of redox-sensitive factors, including activator protein 1 (AP-1) and nuclear factor κ B (NF- κ B), follows the aforementioned membrane signaling (Schreck *et al.*, 1991). The similarities with NO-mediated responses can be readily seen when it is considered that NO has been shown to induce membrane peroxidation and to modulate ion channels, G proteins, kinases, and AP-1/NF- κ B (Radi *et al.*, 1991; Tabuchi *et al.*, 1994; Lander *et al.*, 1993). More specifically, NO, both exogenous and cell generated, has been shown to inactivate protein kinase C (PKC), directly activate G proteins, and induce nuclear translocation of NF- κ B (Gopalakrishna *et al.*, 1993; Lander *et al.*, 1993). Interestingly, PKC activation suppresses the development of apoptosis in several models, including its induction by NO (Messmer *et al.*, 1995), presumably through binding and activation of AP-1 by TRE (Lucas *et al.*, 1994; Walker *et al.*, 1993). AP-1, in turn, has been characterized as an antiapoptotic and antioxidant responsive factor that maps to a negative response site in the promoter region of the *c-myc* gene, the expression of which correlates with the initiation of apoptosis in T-cell hybridomas (Walker *et al.*, 1993). It can be proposed, then, that by inactivating PKC NO may suppress the structuring of a functional AP-1 transcription factor and thus block the expression of "protective" genes. Alternatively, NF- κ B has been demonstrated to be an oxidative-stress responsive element, which translocates extensively to the nucleus following cellular exposure to oxidants and presumably upregulates the transcription of "death genes" (Schreck *et al.*, 1991).

Insight into the genetic regulation of apoptosis has also been gained from the identification of pro- and antiapoptotic gene products (Stewart, 1994; Hawkins and Vaux, 1994; Canman and Kastan, 1995). In regard to NO-mediated apoptosis, Messmer *et al.* (1994) first reported a correlation be-

tween NO exposure and the expression of p53 in studies using RAW 264.7 and RINm5F cells. The nuclear phosphoprotein p53, which was originally characterized as a tumor suppressor agent, acts both as a sequence specific transcription factor to block cells in the G₁/S transition in response to DNA damage and as a trigger for apoptosis (Canman and Kastan, 1995; MacLeod *et al.*, 1990). Although the mechanism of action of p53 in determining these alternative paths of proliferation block or apoptosis remain unclear, it is thought that this gene product can induce apoptosis through altering the balance of the anti- and proapoptosis gene products bcl-2 and Bax (Canman and Kastan, 1995; MacLeod *et al.*, 1990). Indeed, treatment of cells with the NO donor agents S-nitrosoglutathione or spermine-NO resulted in the accumulation of Bax (Messmer *et al.*, 1996a). Although these results suggest a role for p53 in the induction of apoptosis by endogenous or exogenous NO, treatment of the p53-negative cell line U937 with S-nitrosoglutathione also resulted in the characteristic laddering of DNA that is a hallmark of apoptosis (Messmer and Brüne, 1995).

In contrast to the proapoptotic effects of p53, the expression of the protooncogene *bcl-2* has been shown to prevent apoptosis resulting from oxidative injury, growth factor withdrawal, γ irradiation, heat shock, and the application of certain chemotherapeutic drugs (Hawkins and Vaux, 1994). Experiments in our laboratory explored whether the overexpression of *bcl-2* conferred cell immunity from NO-mediated apoptosis (Albina *et al.*, 1996). In these experiments, P815 cells transfected with whole-length human *bcl-2* were exposed to NO liberated from SNAP. Transfected cells were resistant to a wide dose of SNAP (0–1 mM) present during an overnight culture in terms of DNA fragmentation. They were, however, only partially protected from SNAP-dependent cell lysis. In regard to biologically relevant concentrations of NO, the *bcl-2* transfectants were almost completely protected from NO-associated cytotoxicity when exposed to activated murine peritoneal macrophages (Albina *et al.*, 1996).

The mechanism of action of *bcl-2* remains unclear (Korsmeyer *et al.*, 1995). Evidence for and against a role for this mitochondrial membrane protein as an antioxidant has been presented (Hockenbery *et al.*, 1990, 1993; Jacobson and Raff, 1995; Muschel *et al.*, 1995). Bcl-2 has been shown, in addition, to prevent the release of cytochrome *c* from mitochondria and to block the cleavage of PARP in NO-producing cells that is putatively associated with the activation of caspase 3 (Kim *et al.*, 1999). Regardless of its mechanism of action, the observation that *bcl-2* affords certain protection from NO-dependent apoptosis has been confirmed by others (Messmer *et al.*, 1996b; Genaro *et al.*, 1995; Xie *et al.*, 1996; Ringeaud *et al.*, 1995).

Although the prominent nuclear alterations found in apoptotic cells attracted attention to the endonucleases that ultimately result in the internucleosomal cleavage of DNA that characterizes apoptotic death, more recent reports have centered on the role of a variety of proteases, including serine proteases, calpains, and caspases, thought to convey apoptotic signals received at the cell membrane by initiating

a complex intracellular cascade of activating and inactivating proteolytic events. Progress has been particularly rewarding in the understanding of the caspases, a family of at least 10 proteases maintaining homology with death-specific gene products originally described in *Caenorhabditis elegans* (see Cohen, 1997, for a review). These proteases are produced as inactive zymogens, become activated through proteolytic cleavage, and are associated with promotion of cell death. Several inducers of apoptosis, including Fas ligand or Fas cross-linking, actinomycin D, and etoposide, have been shown to result in activation of caspases.

With regard to the dual effect of NO as promoter or suppressor of apoptosis, reports indicate the ability of this mediator to stimulate or suppress the activation of caspases. Considering evidence consistent with NO stimulation of caspase activity, human leukemic lymphocytes were shown to undergo apoptosis when exposed to a NO donor; apoptosis correlated with activation of caspase 8 and was prevented by a broad-spectrum caspase inhibitor (Chlichlia *et al.*, 1998). Messmer and Brüne (1996) reported the detection of PARP cleavage in RAW 264.7 cells expressing iNOS or exposed to NO donor agents. The inactivating cleavage of PARP is known to reflect the activation of ICE (interleukin 1- β -converting enzyme)-like caspases, most likely caspases 3 and 7 (Cohen, 1997). Interestingly, cleavage of PARP was suppressed by transfection with *bcl-2*. Providing further connections between NO-dependent apoptosis and caspase activation, the activation of caspase 3 was demonstrated together with the accumulation of p53 and reduction of *bcl-2* in rabbit aortic vascular smooth muscle cells treated with the NO donor agent SNAP (Nishio and Watanabe, 1998). Brockhaus and Brüne (1998) showed that exposure of the p53-negative human leukemic U937 cells to NO donor agents activated caspase 3-like activity that resulted in cleavage of PARP. In this study the authors also reported that NAC prevented apoptosis and the cleavage of PARP. Most importantly, and in agreement with the results of others (Wang *et al.*, 1997), they concluded that PARP cleavage is not essential for the progression of apoptosis, as caspase inactivation prevented apoptosis but not PARP cleavage. Treatment of HL-60 cells with peroxynitrite (100 μ M) also induced the activation of caspase 3 (Lin *et al.*, 1998).

As mentioned before, NO can act as a negative regulator of apoptosis. Either endogenous or exogenously provided NO has been shown to halt apoptosis induced by a variety of triggers in a number of cell types including hepatocytes, endothelial cells, cardiac myocytes, splenocytes, B cells, and eosinophils (Mannick *et al.*, 1994; Kim *et al.*, 1995; Dimmeler *et al.*, 1997). Infusion of a NO donor agent was also able to inhibit hepatic apoptosis in rats challenged with TNF- α or galactosamine (Kim *et al.*, 1997). This protective effect of NO was shown to coincide with suppression of intracellular caspase 3 proteolytic activity.

NO donor agents were shown to inhibit caspase 3 when its activity had been previously increased by treatment of U937 cells with actinomycin D (Mohr *et al.*, 1997). The inhibitory effects on caspase 3 of the NO donor compounds in lysates from actinomycin D-treated cells could, in the

case of GSNO, spermine-NO, and BF₄NO, be reversed with dithiothreitol. The inhibition of caspase 3 activity by 1,3-morpholino-sydnonimine hydrochloride (SIN-1) or peroxynitrite could not be reversed by the reducing agent. These findings suggested the S-nitrosylation of active site cysteine in caspase 3 as the reversible mechanism of enzyme inhibition, and the further oxidation of this site as the irreversible mechanism. Most interestingly, whereas the addition of GSNO to intact cells cultured with actinomycin D reduced caspase 3 activity, its use in untreated cells actually increased caspase 3 activity. At the biochemical level, the inhibition of seven different recombinant caspases by a NO donor agent was shown together with its reversal by dithiothreitol, indicating S-nitrosylation of the catalytic cysteine residue (Li *et al.*, 1997). In addition, caspase 3 activity in lysates of TNF- α /actinomycin D-treated hepatocytes was suppressed by the addition of a NO donor compound to the culture medium. Work from the same laboratory reported by Kim *et al.* (1997) extended these observations by demonstrating in rat and mouse hepatocytes that the induction of NOS or the addition of NO donor agents prevented spontaneous, TNF- α -associated, and anti-Fas antibody-induced apoptosis, and the inhibitory S-nitrosylation of caspase 3 by NO *in vitro* and *in vivo*. These authors, in addition, proposed an additional mechanism for the antiapoptotic effect of NO in these cells that is dependent on the production of cGMP and does not involve S-nitrosylation. In this regard, others showed that low concentrations of NO donor agents could inhibit TNF- α -induced apoptosis in endothelial cells through a cGMP-dependent mechanism, but that higher concentrations of NO donor compounds induced apoptotic death in the cells. Additional results obtained in pulmonary artery endothelial cells subjected either to adenoviral transfer of inducible NOS or to NO donor exposure indicated these cells to be protected from LPS-mediated apoptosis (Ceneviva *et al.*, 1998). Interestingly, no correlation was found between the protective effect of NO and the induction of putatively protective genes, including those for HSP-70, metallothionein, heme oxygenase-1, or *bcl-2*. In contrast, NO prevented the activation of caspases in a dithiothreitol-sensitive fashion.

The inhibitory effects of endogenous and exogenous NO on caspase 3 were also demonstrated in TNF- α -treated human endothelial cells (Dimmeler *et al.*, 1997). Protection by NO from Fas-mediated apoptosis has been reported in human hemopoietic cell lines (Mannick *et al.*, 1997; Dimmeler *et al.*, 1998). Ogura *et al.* (1997), in turn, reported the inhibition of recombinant caspase 3 in lysates of cells treated with vincristine by a NO donor agent. Addition of GSH in rather modest concentrations to the assay mixture prevented the inhibitory effect of the NO donor, supporting the concept that the inhibition of caspase 3 activity by NO is under redox control and mediated through the S-nitrosylation of active site cysteines.

Although the findings reviewed so far associate caspase 3 inhibition with suppression of apoptosis, it has been shown that culture of Jurkat cells with SNAP is associated with necrotic cell death despite inhibition of caspase 3 activation. The dose-dependent capacity of NO to induce apoptosis or necrosis has been also shown for peroxynitrite in cell cul-

tures; exposure to this product at concentrations lower than 1 mM resulted in apoptosis, whereas concentrations higher than 2 mM induced cell necrosis (Estévez *et al.*, 1995). Similar findings in thymocytes were reported by others (Virág *et al.*, 1998). Shen *et al.* (1998), in turn, reported that low concentrations of SNAP inhibited TNF- α -induced apoptosis in a cGMP-dependent manner, but also that higher concentrations of the NO donor agent actually induced apoptosis in their human endothelial cell preparations.

Evidence at hand, therefore, indicates that NO can both activate and inhibit caspases, or at least caspase 3. This ability of NO may relate to its capacity to induce or prevent apoptosis. It must, however, be kept in mind that cells lacking PARP, the putative substrate for activated caspase 3, do undergo apoptosis after treatment with TNF- α , anti-Fas, γ irradiation, and dexamethasone (Wang *et al.*, 1997).

Recognition of Apoptotic Cells by Macrophages and Dendritic Cells: Mechanisms and Relevance to Antitumor Immune Responses

The removal of apoptotic cells prior to dissolution of the plasma membrane prevents the release of potentially toxic and/or immunogenic molecules, which may instigate or exacerbate tissue injury. It is easy, in this context, to appreciate the value of cleanly removing senescent neutrophils from a site of acute inflammation, or eosinophils from a local site of atopy. Macrophages have been shown to internalize apoptotic cell debris without elicitation of a phlogistic response, in distinction to phagocytosis of pathogens via Fc or complement receptors. In fact, phagocytosis of apoptotic material by macrophages actively inhibits production of proinflammatory mediators such as interleukin 1 β (IL-1 β), IL-8, leukotriene C4, and TNF- α while inducing anti-inflammatory products such as transforming growth factor β (TGF- β), prostaglandin E₂ (PGE₂), and platelet-activating factor (Fadok *et al.*, 1998a).

Cells undergoing apoptosis exhibit certain common characteristics, including exposure of anionic phospholipids in the plasma membrane and modification of cell surface carbohydrate moieties (Savill, 1996). A number of receptors have been described on phagocytes that take advantage of these alterations to mediate recognition and removal of apoptotic bodies. These include the vitronectin receptor ($\alpha_v\beta_3$ integrin), CD36, an undefined receptor specific for phosphatidylserine, scavenger receptors, CD14, and a lectin with specificity for *N*-acetylglucosamine or glucosamine (Stern *et al.*, 1996). The receptors for vitronectin and CD36 are thought to form a complex on the cell surface capable of recognizing thrombospondin (TSP), a macrophage secretory protein. TSP, or a 140-kDa COOH-terminal domain proteolytic fragment from this protein, in turn forms a bridge between the receptor complex on the phagocyte and the apoptotic cell. There may be a hierarchy of importance among the seemingly redundant battery of apoptotic receptors with CD36 at the top. Several cell types with no capacity for phagocytosis of apoptotic bodies became efficiently

phagocytic when transfected to overexpress CD36 regardless of whether the apoptotic cells were neutrophils, lymphocytes, or fibroblasts (Ren *et al.*, 1995). In other work, blockade of CD36 with specific antibodies inhibited uptake by both $\alpha_v\beta_3$ - and phosphatidylserine-dependent pathways (Fadok *et al.*, 1998b). The mechanism by which CD36 interacts with these molecules at the cell surface is not yet understood.

The receptor–ligand interactions just described suggest a redundant system of recognition of apoptotic cells, which may contribute to the overall efficiency of this process. However, the mechanisms that prevail are regulated at the level of the phagocytic cell and, perhaps, at the level of the type of apoptotic target cell. Monocytes and macrophages utilize different mechanisms depending on their state of activation. For example, human peripheral mononuclear cells use primarily the CD36/ $\alpha_v\beta_3$ /TSP mechanism for recognition of apoptotic neutrophils, but they switch to phosphatidylserine-mediated recognition on activation (Fadok *et al.*, 1998b). In an animal model, resident peritoneal, immune-activated, and wound-derived macrophages all used distinct mechanisms in the phagocytosis of aged, apoptotic neutrophils (Meszaros *et al.*, 1999).

Dendritic cells share a common bone marrow-derived lineage with macrophages, but they express a distinct functional and phenotypic profile. They are particularly well suited for a specialized role in antigen presentation, as they express high levels of cell surface major histocompatibility complex (MHC) antigens and costimulatory molecules and, as a result, are the most potent antigen-presenting cells for the initiation of T-cell-dependent immune responses (Steinman, 1991). Dendritic cells can be found in immature and mature states. When in their immature state, dendritic cells are distributed widely in peripheral tissues but decidedly outside lymphoid tissues. These cells are also capable of phagocytosis of apoptotic cells, a function that may be restricted to dendritic cells in the immature state (Albert *et al.*, 1998). Immature dendritic cells have been shown, in addition, to acquire antigens expressly from ingested apoptotic, but not necrotic, cells. Once engorged, dendritic cells mature as they migrate to regional lymph nodes, where processed antigen is presented in the context of MHC class I molecules to CD8⁺ cytotoxic T cells. Although the multitude of receptors capable of recognizing apoptotic ligands endows the macrophage with a highly efficient capacity for bulk clearance of apoptotic cells, the dendritic cell may prove to be the effector cell of choice for presentation of antigen to the immune system. As is the case with macrophages, immature dendritic cells demonstrate high levels of cell surface CD36; however, the α_v integrin chain in these cells is expressed in the context of β_5 , forming the $\alpha_v\beta_5$ integrin, which is not found on macrophages (Albert *et al.*, 1998). Antibodies blocking either $\alpha_v\beta_5$ or CD36 are sufficient to inhibit phagocytosis of apoptotic cells, raising the possibility of intermolecular cooperation as seen for $\alpha_v\beta_3$ and CD36 on macrophages.

Dendritic cells, in response to allogeneic T cells or immunomodulators such as LPS and IFN- γ , express iNOS and produce NO in levels that rival macrophages (Lu *et al.*,

1996). As in the case of the macrophage, dendritic-cell derived NO inhibits lymphocyte proliferation and induces apoptosis in the cells that produce it (Lu *et al.*, 1996). However, there is no evidence to suggest that a dendritic cell can distinguish a transformed from a normal cell and utilize NO as an effector molecule to manifest its own tumoricidal effect. Absent also is any evidence that dendritic cells cooperate with tumoricidal macrophages by ingesting apoptotic fragments of targeted tumor cells and then migrating to the nearest lymph node to initiate a tumor-specific cytotoxic T-lymphocyte response. Whether the tumor itself has an active role in suppressing such a pathway to immunization is unclear, although some tumors are capable of elaborating factors such as IL-10 that could limit dendritic cell differentiation and function (Schuler and Steinman, 1997). A large body of evidence is being accrued which suggests that dendritic cells primed with tumor antigens *ex vivo* generate a potent antitumor response when returned to the tumor-bearing host (Schuler and Steinman, 1997). Clinical studies are currently underway exploring the usefulness of dendritic cells as a basis for immunotherapy and tumor vaccination protocols.

As described earlier, the caspases are an integral aspect of the cellular decision to abandon the efforts of PARP to repair damaged DNA and proceed with the apoptotic pathway. Caspase activity marks one of the earliest steps in the cidal cascade, such that interference with caspase activity may be a mechanism by which NO mediates cytoprotection. This protection may also be manifested in another way. Caspase activity can be detected prior to morphologic evidence of apoptosis including chromatin condensation, nuclear fragmentation, mitochondrial potential alteration, and translocation of phosphatidylserine to the outer leaflet of the plasma membrane. Interestingly, cells that demonstrate caspase activity but no other morphologic evidence of apoptosis are fodder for phagocytosis. Therefore, the cytoprotective effect of NO through caspase inhibition may include protection from premature engulfment by tumor-associated macrophages (Durrieu *et al.*, 1998).

NO, Tumor Cell Apoptosis, and the Human Macrophage

Although the concept of the macrophage as a cytotoxic effector for tumor cells is well established, the limitations of this model must be kept in mind. First, the nonspecific elimination of tumor cells by macrophages is anatomically restricted to the site where macrophages are activated. Indeed, although the systemic distribution of macrophage-activating agents (i.e., bacillus Calmette-Guerin [BCG]) could result in some degree of systemic macrophage activation, most macrophages endowed with cytotoxic activity congregate at the site where the activating agent is delivered. Second, macrophage activation for cytotoxic activity appears to require the action of T-cell-derived cytokines, bacterial products, or other exogenous agents. How this activation would occur at

the tumor site remains unclear. Most importantly, the presence of macrophages within tumors (tumor-associated macrophages or TAMs) has been interpreted as both suppressive and supportive of tumor growth. In connection with presumed antitumor effects of TAMs, the production by these cells of cytotoxic molecules (NO, TNF- α , etc.) may be envisioned as antagonistic to tumor development. The release from TAMs of matrix metalloproteinases, angiogenic factors, or growth factors may, alternatively, promote tumor growth.

Within the specific area of concentration of this chapter, that is, NO cytotoxicity for tumor cells, remarkably few publications have addressed the potential role of NO as a cytotoxic molecule *in vivo*. Two publications deserve special discussion. DiNapoli *et al.* (1996) reported that TAMs obtained from a transplantable mammary carcinoma in mice were unable to produce NO and lyse tumor cells even after treatment with IFN- γ and endotoxin. The same TAMs shown not to be able to express NOS, however, were capable of phagocytosis, showed adherence to plastic, and produced as much IL-6 as those obtained from other anatomical sites in the animal. Thus, whether macrophages actually present at a tumor site can express NOS remains open to investigation.

In an additional *in vivo* study, Gal *et al.* (1997) injected SJL mice with superantigen-bearing RcsX lymphoma cells. Growth of this tumor results in a systemic inflammatory reaction in the hosts. Histochemical interrogation of spleens and lymph nodes from these animals revealed intense iNOS staining in macrophages and apoptotic features and 3-nitrotyrosine staining in neighboring cells. Interestingly, iNOS-positive macrophages did not present apoptotic features, and the apoptotic cells did not show evidence of direct DNA damage as measured by 8-oxoguanidine accumulation. Unfortunately, the authors did not report on the presence of iNOS-positive macrophages or apoptotic cells at the site of tumor development.

It is particularly important to highlight that all observations described thus far on the induction of apoptosis in tumor cells through macrophage-derived NO have used rodent macrophages as the effector cells. Not one report has demonstrated the capacity of human effectors to elicit NO-dependent tumor cell apoptosis.

In this connection, the remarkable weakness of data supporting the production of NO by human monocytes and macrophages has been reviewed (Albina, 1995). Moreover, the report by Schneemann *et al.* (1997) of a nonenzymatic explanation for the accumulation of NO by products in cultures of human monocytes following stimulation with IL-4 refutes one of the more firmly established models for the induction of NOS in human cells (Mautino *et al.*, 1994; Defer *et al.*, 1994).

With regard to human neoplastic disease, cells identified as macrophages were shown to contain immunoreactive inducible NOS in stromal tissue in breast carcinoma (Thomsen *et al.*, 1995). Additionally, calcium-dependent NOS activity was found in those as well as in gynecological and central nervous system tumors (Thomsen *et al.*, 1994; Cobbs *et al.*,

1995). The potential tumor-supporting role of endothelial-type NOS in these malignancies through its vasodilating activity or through the proposed suppression of caspases by low levels of NO remains to be determined.

As far as can be known today, the high-output production of NO through the inducible form of NOS appears to be restricted to macrophages of certain species. If indeed human monocytes or macrophages are capable of releasing low levels of NO, as proposed by some (Albina, 1995), then they may, along the lines discussed in the previous section, be protective rather than toxic toward tumor cells.

Summary

Results reviewed here address the cytotoxicity of macrophage-derived NO and the mechanisms for NO-dependent apoptosis. Although data obtained using wound cells and nuclear factor IL-6-negative macrophages suggest NO may be necessary but not sufficient to explain macrophage cytotoxicity, no doubts remain that at least chemically derived NO induces apoptosis in certain tumor cells. The nature of the NO derivatives ultimately responsible for the induction of apoptosis under physiological conditions, as well as the mechanisms through which apoptotic pathways are induced, awaits clarification. Most interestingly, reports from multiple laboratories indicate that selected cell types can resist NO using innate or acquired defense mechanisms. The relevance of these mechanisms to tumor development remains to be explored. Last, regarding the relevance of NO to human macrophage-dependent cytotoxicity, clarification of the production of NO by these cells will be required before firm conclusions can be reached regarding a role for NO in human neoplastic disease.

DIVERSE PHYSIOLOGICAL AND PATHOPHYSIOLOGICAL ROLES FOR NITRIC OXIDE (NO) HAVE BEEN IDENTIFIED IN MANY TISSUES, INCLUDING THOSE OF A VASODILATOR, NEUROTRANSMITTER, ANTIMICROBIAL AGENT, IMMUNOMODULATOR, AND INTRACELLULAR SIGNALLING MOLECULE, ALL OF WHICH MAY OPERATE IN THE GUT. THUS, IN THE GASTROINTESTINAL TRACT, NO CAN AFFECT GASTRIC ACID SECRETION AND BLOOD FLOW AS WELL AS MUCUS AND BICARBONATE SECRETION. NO ALSO AFFECTS INTESTINAL MOTILITY AND SPHINCTER TONE, MICROCIRCULATION, ELECTROLYTE SECRETION, AND WATER ABSORPTION. MANY OF THESE CHANGES IN RESPONSE TO STIMULATION BY NO ARE TRANSDUCED VIA ACTIVATION OF SOLUBLE GUANYLATE CYCLASE. NO AND NO DONORS CAN BRING ABOUT MUCOSAL PROTECTION AGAINST CHALLENGE BY AFFECTING SUCH PROCESSES. NO CAN ALSO AFFECT ADHESION OF WHITE CELLS TO THE MICROVASCULAR ENDOTHELIUM, AN EVENT THAT CAN MODULATE TISSUE INJURY. IN THIS CHAPTER, THE ROLE OF NO FORMED BY THE THREE ISOFORMS OF NOS IN THE GASTROINTESTINAL TRACT IN THE MAINTENANCE OF PHYSIOLOGICAL FUNCTION AND MUCOSAL INTEGRITY, AS WELL AS THE INVOLVEMENT OF NO IN PATHOLOGICAL PROCESSES INCLUDING INTESTINAL CYTOTOXICITY, TISSUE INJURY, AND INFLAMMATION, HAS BEEN REVIEWED.

Introduction

Nitric oxide (NO) has been shown to play a diverse range of roles in biological tissues and organs, including those in the gastrointestinal tract. Diverse physiological and pathophysiological roles for NO have been identified, including those of a vasodilator, neurotransmitter, antimicrobial agent, immunomodulator, and intracellular signaling molecule, all of which may operate in the gut. NO, which is formed by the actions of three distinct isoforms of the synthetic enzyme

NO synthase (NOS) [endothelial NOS (eNOS), neuronal NOS (nNOS), and inducible NOS (iNOS)], can be detected in a wide range of cell types, including endothelial cells, macrophages, neurons, hepatocytes, fibroblasts, epithelial cells, and smooth muscle cells. In the gastrointestinal tract, NO acts on several of these cell types to bring about changes in secretion, motility, blood flow, electrolyte and water absorption, mucosal protection, and inflammation. Many of these changes in response to stimulation by NO are transduced via activation of soluble guanylate cyclase.

This chapter reviews studies on the role of NO formed by the three isoforms of NOS in the gastrointestinal tract in the maintenance of physiological function and mucosal integrity. In addition, the involvement of NO in pathological processes such as inflammation will be reviewed.

Physiological Actions of NO in the Gut

Blood Flow

Nitric oxide has been shown to play an important role in modulating vascular tone within the gastrointestinal circulation. Different physiological stimuli such as shear stress, changes in Ca^{2+} concentration, or changes in oxygen tension may stimulate NO release.

Administration of the isoform-nonspecific NOS inhibitor N^G -monomethyl-L-arginine (L-NMMA) reduces resting gastric mucosal blood flow in experimental studies, suggesting the involvement of endogenous NO in modulating the resting gastric microcirculation. Similarly, L-NMMA and N^G -nitro-L-arginine methyl ester (L-NAME) have been shown to increase vascular resistance in the mesenteric circulation and can reduce blood flow in the small and large intestine.

In the stomach, the increase in gastric mucosal blood flow caused by stimulants such as pentagastrin can be reduced without any influence on acid secretion by administration of L-NAME, an effect which can be reversed by coadministration of L-arginine. The back-diffusion of H^+ leads to an increase in gastric blood flow, and this microvascular response can be inhibited by L-NAME treatment, including a protective hyperemic response. These findings suggest that NO, which may interact with endogenous prostaglandins, is involved in the regulation of gastric blood flow.

The esophagus, like the stomach, is also able to resist damage due to refluxed acid by increasing mucosal blood flow. This hyperemic response is preceded by luminal histamine release and can be attenuated by mast cell stabilization, histamine H_1 receptor blockade, and NOS inhibition. NOS inhibition also prevents the histamine release, suggesting that mast cell-derived histamine acts via an NO-dependent mechanism in this response.

In the intestine NO also plays an interactive role in the regulation of blood flow. Sympathetic neurogenically mediated vasoconstriction of intestinal arterioles increases during NO synthase inhibition, and this augmented response can be reversed by exposure to L-arginine. The most likely source of this NO released during increased sympathetic nerve activity is the microvascular endothelium.

NO also appears to be involved in the intestinal hyperemia in response to luminal instillation of certain foodstuffs. Thus, glucose administration into the ileal lumen results in an increase in blood flow, which was blocked by L-NAME. It is not yet known if glucose causes a direct production of NO or whether epithelial cells transduce a vasodilator signal through vascular endothelium-derived NO during postprandial intestinal hyperemia.

NO and Cell Adhesion

Within the vasculature, NO can exert a variety of effects apart from its influence on vasomotion, including the inhibition of platelet aggregation and the attenuation of leukocyte and endothelial interaction. For a leukocyte to adhere to the endothelial lining, it must initially make a brief tethering interaction with endothelium, which then develops into a rolling interaction. It has been demonstrated experimentally that inflammation following administration of a NOS inhibitor is associated with enhanced leukocyte and endothelial interaction and with increased leukocyte adherence and emigration.

Furthermore, inhibition of NO synthesis promotes the adhesion molecule P-selectin-dependent leukocyte rolling, suggesting that NO may be a homeostatic regulator of leukocyte rolling under normal conditions. Administration of exogenous NO decreases leukocyte rolling in acute inflammation induced by a variety of conditions including ischemia-reperfusion and reactive oxidant administration.

NO and Gastric Acid Secretion

Whereas inhibition of NO formation does not directly modulate resting or stimulated gastric acid secretion, endogenous NO appears to be involved in the acute antisecretory action of agents such as lipopolysaccharide and cytokines or in moderate hypothermia, acting through mechanisms in the brain. It has also been observed that NO synthase inhibition could reduce acid secretion in response to a protein meal or gastrin administration.

Direct administration of NO donor agents can reduce vagally mediated acid secretion as well as histamine-stimulated acid secretion. It has also been demonstrated that NO donor agents can inhibit pentagastrin-stimulated acid secretion in doses that did not affect blood flow. Such an effect may reflect, in part, suppression of histamine release from enterochromaffin-like cells. Furthermore, high concentrations of NO donor agents can inhibit parietal cell activity *in vitro*, suggesting a direct action of NO on acid secretory activity.

NO and Gastroduodenal Secretion of Mucus and Bicarbonate

The continuous viscoelastic layer of gastric mucus over the mucosa has been shown to play an important role in mucosal protection against topical irritation by noxious agents in the lumen. Furthermore HCO_3^- secreted from the duodenal epithelial cells into the mucous gel has been shown to establish a pH gradient in the gel, thereby providing a line of defense against gastric acid. NO donor agents such as isosorbide dinitrate and *S*-nitroso-*N*-acetyl-penicillamine (SNAP) have been shown to increase mucus gel thickness. NO synthase inhibitors have also been shown to reduce the ability of mucosal cells to secrete and synthesize mucus. Furthermore, treatment with the NO substrate L-arginine can

reverse the reduction in gastric cellular mucous secretion in response to hypoxia–reoxygenation that has been observed in some *in vitro* situations.

It has been demonstrated that NO mediates mucus secretion in response to a number of stimulatory agents such as gastrin, histamine, and acetylcholine. Both acute and chronic inhibition of NO synthesis can reduce mucus secretion *in vivo*.

Inhibition of NO synthase activity has been shown to increase duodenal alkaline secretion, suggesting that endogenous NO may modulate the basal secretion of HCO_3^- . This inhibition may reflect suppression of a stimulatory nicotinic receptor-dependent neural mechanism.

Luminal acid formation can increase mucosal NO output, and this response can be inhibited by L-NMMA treatment. Furthermore, L-NMMA may reduce the acid-stimulated increase in alkaline secretion. Similarly, luminal administration of a NO donor agent has been shown to increase mucosal HCO_3^- secretion in the dog. The acid-induced increase in HCO_3^- secretion can be inhibited by an extract of *Helicobacter pylori*, and this effect could be overcome by L-arginine.

Mucosal damage in response to a hyperosmotic challenge also increased gastroduodenal HCO_3^- secretion, and this effect was attenuated by treatment with a NO synthase inhibitor. Thus, NO appears to mediate the alkaline secretory response to luminal acid and as a consequence of an injurious challenge to the stomach.

NO and Intestinal Electrolyte and Water Secretion

It is now well established that L-arginine and NO synthase inhibitors are able to influence intestinal secretion. However, the findings are contradictory and vary depending on the segment of intestine studied, the animal species involved, and other experimental conditions. The latter include *in vivo* or *in vitro* conditions, intact or stripped tissues, and the type of challenge used. Overall, given the data it can be suggested that under physiological conditions a NO-dependent proabsorptive tone exists. This conclusion is based on a number of findings that NO synthase inhibitors induce net fluid and electrolyte secretion *in vivo* in several animal species. However, some reports suggest that an increase in NO formation may also be capable of evoking net secretion in the gut. A notable exception is the diarrhea produced by bacterial enterotoxin, in which NO may exert a proabsorptive action. Because NO may mediate both secretagogue and proabsorptive actions within the intestine, it will be necessary to identify more precisely the conditions under which NO exerts these diverse actions.

Administration of NO-generating compounds can stimulate intestinal water and electrolyte absorption. Thus luminal administration of L-arginine or SNAP increases water and electrolyte absorption. Furthermore a NO donor agent can attenuate the secretion and permeability changes induced in the rat ileum by administration of *Clostridium difficile* toxin A. Similarly, sodium nitroprusside treatment was shown to

inhibit jejunal secretion in response to *Escherichia coli* enterotoxin.

These data support the potential therapeutic use of NO-generating compounds in the treatment of some pathological hypersecretory states. Intrarectal administration of NO donor agents in animals can induce increases in insulin absorption as well as high-molecular-weight dextran. Such information thus suggests that NO donor agents may have the potential to act as potent absorption enhancers in a clinical setting.

NOS INHIBITION AND DIARRHEAL DISORDERS

Under physiological conditions an NO-dependent proabsorptive tone exists in the intestine. However, in some pathological states, including many different experimental models of inflammatory bowel disease in mouse, rat, guinea pig, and monkey, as well as in tissue from patients with Crohn's disease and ulcerative colitis, NO can be produced at higher concentrations capable of evoking net secretion. Such NO appears to contribute to the diarrhea associated with a number of models of intestinal inflammation.

Furthermore, elevated activity of NOS is associated with the laxative action of several intestinal secretagogues, including castor oil, phenolphthalein, bisacodyl, magnesium sulfate, bile salts, senna, and cascara. Studies using isoform-selective and -nonselective inhibitors have indicated that inhibition of NOS effectively ameliorates the intestinal secretion depending on the model evaluated. Although L-NAME or L-NMMA effectively reduces the diarrheal response to the laxatives listed, inhibitors of iNOS are only effective against bile salt- and cascara-mediated secretion.

NO and Gastrointestinal Motility

Nitric oxide has been shown to exert some potent actions on enteric smooth muscle, particularly relaxation. Strong evidence demonstrating that NO is one of the key transmitters of nonadrenergic noncholinergic (NANC) nerve-induced relaxation of gastrointestinal smooth muscle has accumulated. Indeed, such nerves have been referred to as nitrergic neurons. Evidence for such nitrergic innervation includes the demonstration that NOS immunoreactivity can be detected in gastrointestinal myenteric and submucosal neurons; also, NO release in response to electrical field stimulation can be inhibited by neural toxins including tetrodotoxin. NO, when acting as a mediator of NANC relaxation of basal tone as well as following neuronal stimulation, has been demonstrated in various segments of the gastrointestinal tract, including duodenum, ileum, ileocecal junction, colon, esophagus, and lower esophageal sphincter.

GASTRIC AND INTESTINAL MOTILITY

NO has been proposed as a physiological mediator of the regulation of gastric emptying in response to various luminal nutrients in the stomach and duodenum. In the esophagus, NO plays an important role in the mediation of propulsive activity by regulating the period and gradient between the

onset of a swallow and contractions of the esophageal circular muscle. Similarly, NO has been suggested to be involved in the coordination of peristaltic activity in guinea pig intestine via a dual excitatory and inhibitory effect on intestinal motility. The excitatory effect may involve cholinergic motor neurons, whereas the inhibitory effect may reflect direct relaxation of intestinal muscle.

NO has also been linked with the slowly migrating, cyclic peristaltic wave associated with the interdigestive state in most mammals. This interdigestive migrating complex involves a number of components, including contraction originating in the stomach and propagating to the terminal colon that is regulated by the gut hormone motilin. NO has been shown to influence these contractions, as NO synthase inhibition results in their appearance even after feeding. Inhibition of NO synthesis was also found to stimulate motilin release via cholinergic pathways independent of the vagus. The contractions induced by NO synthase inhibition appear to involve activation of 5-hydroxytryptamine (5-HT) receptors.

The mechanisms of NO-induced relaxation of gastrointestinal smooth muscle are a subject of much investigation. NO may have some association with vasoactive intestinal peptide (VIP), a signaling peptide that has also been designated as a NANC mediator. However, it has also been demonstrated that although vagal activation evokes both VIP and NO release, there is no evidence for any interaction, and the relaxation induced by VIP does not involve NO.

The contractile response of intestinal tissue to a NO synthase inhibitor can be inhibited by tetrodotoxin or hexamethonium, indicating a neural involvement. Furthermore, NO relaxes circular muscle of the rat forestomach both directly at a muscular site and indirectly via inhibition of acetylcholine release. A similar neural mechanism has been proposed for NO-mediated inhibition of duodenal motility. In contrast, it has been shown that NO does not inhibit acetylcholine release in guinea pig ileal circular muscle and may inhibit the release of tachykinins that act on NK1 receptors.

In pathological conditions associated with ileus, complete or partial gastrointestinal motor dysfunction occurs. Studies of canine gastrointestinal motility during periods of endotoxemia have shown that gastric emptying and colonic transit are slowed. Similarly, the interdigestive migrating complex is delayed. These changes have been attributed to NO production induced by endotoxin. The lipopolysaccharide-induced changes in intestinal transit can be reversed by administration of a NO synthase inhibitor, and the effects on the interdigestive complex are negated.

NO donor agents have been used in the treatment of functional disturbances of gastric motility and emptying. NO can suppress fundic, antral, pyloric, and duodenal contractions and inhibit pyloric motility in response to intraduodenal triglyceride. Similarly, NO release following glyceryl trinitrate administration slows the rate of gastric emptying and decreases antral motor activity. Similarly, L-arginine administration can reduce antral motility changes in response to a liquid test meal.

GALLBLADDER AND SPHINCTER OF ODDI

Release of bile into the duodenum is controlled by hepatic bile secretion, gallbladder contraction, and the sphincter of Oddi. The hormone cholecystokinin is considered to be the physiological stimulant for postprandial gallbladder contraction and sphincter relaxation. Studies have shown that the action of cholecystokinin on the sphincter of Oddi is mediated through NANC nerves, and NO is an important component of the pathway.

In humans, administration of a NO donor agent can produce gallbladder dilation in the fasting state, reduce postprandial emptying, and inhibit the motility of the sphincter of Oddi as well. It has been proposed that glyceryl trinitrate would be useful during endoscopic retrograde cholangiopancreatography cannulation and gallstone extraction. Although it has been considered that long-term nitrate therapy and the resultant inhibition of gallbladder motility may be a risk factor in the accelerated genesis of gallstones, the relaxant effect of glyceryl trinitrate and other NO donor agents, including isorbide dinitrate, has been shown to reduce the pain associated with acute biliary colic.

ESOPHAGUS AND LOWER ESOPHAGEAL SPHINCTER

NO may play a role in the regulation of esophageal motility. Experimental findings suggest that, at least in part, NO may be responsible for the onset of the swallow and coordinated occurrence of contractions in the circular smooth muscle. In the esophagus, endogenous NO has been implicated in the development of a latency period and latency gradient and in the regulation of the amplitude of esophageal body peristalsis. Furthermore, NO has been shown to be a mediator of lower esophageal sphincter relaxation.

In clinical studies, NO donor agents have been utilized in the treatment of diffuse esophageal spasm and achalasia, where there are disturbances of normal esophageal motility. Diffuse esophageal spasm is a functional disorder in which the mechanisms responsible for the physiological timing of contractions are dysfunctional. Administration of NO to these patients significantly prolonged the latency period, restored the normal peristaltic contractions, and reduced their duration, thus abolishing the adverse clinical symptoms. Treatment with L-arginine was ineffective, but this may be anticipated if a functional disruption of the NO pathway exists.

Achalasia is a motor disorder characterized by abnormal peristalsis, elevated pressure of the lower esophageal sphincter, and failure of sphincter relaxation in deglutition. A reduction in NOS-containing neurons has been identified in this disorder in humans. In an animal model of achalasia, the NO donor agent sodium nitroprusside has been shown to reduce resting lower esophageal pressure in the achalasia group as well as in the control group of animals. Furthermore, in patients with achalasia, NO donor agents can induce relaxation of esophageal muscle. Thus, NO donor agents may have important therapeutic benefits in the treatment of esophageal motor disorders.

NOS INHIBITION AND MOTILITY

Because excessive NO may play a role in functional disturbances of gastric and intestinal motility, it is feasible that such disorders may respond to therapy with inhibitors of NOS. The most common disorder in this respect is the rapid transit and disrupted gastrointestinal motility of endotoxemia. This may result from the induction of iNOS, producing excessive NO. Challenge with *E. coli* lipopolysaccharide increased tissue and iNOS activity and the rate of intestinal transit, which was reversed by NOS inhibition. In contrast to the intestine, endotoxin treatment delayed gastric emptying. This effect could be reversed by dexamethasone, perhaps suggesting the involvement of iNOS in this response.

The NO produced by eNOS, although not a disorder of excess NO, facilitates gastric emptying, and this response can be inhibited by isoform-nonspecific NOS inhibitors. This may be clinically useful in the treatment of conditions associated with accelerated gastric emptying, such as those associated with gastroduodenal resective surgery.

Mucosal Protection

Intragastric administration of the glyceryl trinitrate sodium nitroprusside and SNAP can protect against experimentally induced acute gastric mucosal injury induced by topical irritants such as aspirin and by intravenous infusions of endothelin-1, endotoxin, or platelet-activating factor.

In the intestine, administration of NO donor agents provides significant protection against the mucosal and microvascular dysfunction associated with ischemia–reperfusion. Prophylactic administration of L-arginine has been shown to improve intestinal barrier function in experimental animals after mesenteric ischemia. NO administration can also diminish thermal injury-associated venule constriction and irregularity within the gastrointestinal tract. However, local infusion of high doses of an NO donor agent has been shown to cause gastric mucosal damage.

A nitro-derivative of the nonsteroidal anti-inflammatory drug flurbiprofen, which contains a moiety similar to the NO-releasing moieties found in many organic nitrates, not only suppresses gastric prostaglandin synthesis but also causes significantly less hemorrhagic damage than flurbiprofen itself. Similarly, a nitroxy butyl ester derivative of ketoprofen also results in less acute gastric mucosal injury than does its parent compound, while demonstrating comparable anti-inflammatory activity. Nitric oxide-releasing derivatives of aspirin have also been shown to reduce the susceptibility of the stomach to shock-induced damage by inhibiting neutrophil adherence to the vascular endothelium. This class of NO-containing compounds has also been found effective in reducing the extent of intestinal damage in response to endotoxic shock, although the changes in blood pressure and hematocrit were similar to that produced by the parent compound itself.

Pathological Actions of NO in the Gut

Cytotoxic Actions of NO

A wide array of cell types found in the gut, including inflammatory and epithelial cells, can be induced to express iNOS, which then produces large amounts of NO (Fig. 1). Such concentrations of NO may interact with various target molecules such as oxygen, thiol groups, and metals within the prosthetic groups of various enzymes, resulting in their activation or inactivation. NO can react with nonsulfur centers of aconitase of the tricarboxylic acid cycle as well as with complexes I and II of the electron transport chain within target molecules. The inhibition of these essential components of cellular respiration results in depletion of cellular ATP stores with consequent cytotoxicity.

NO may also mediate cytotoxicity by a number of other mechanisms, including impairment of DNA synthesis, direct toxicity through deamination reactions, and possibly more importantly via the potentiation of the toxicity of oxygen radicals. NO can combine with superoxide anion (O_2^-) to form the intermediate peroxynitrite, which is then protonated to peroxynitrous acid under acidic conditions; peroxynitrous acid yields the cytotoxic products hydroxyl radical ($\cdot OH$) and nitrogen dioxide (NO_2). Peroxynitrite can initiate toxic oxidative reactions *in vivo* and *in vitro*. These include initiation of lipid peroxidation, direct inhibition of mitochondrial respiratory chain enzymes, inactivation of glyceraldehyde-3-phosphate dehydrogenase, inhibition of membrane Na^+, K^+ -ATPase, and other oxidative protein modifications. In addition, peroxynitrite is a potent trigger of DNA strand breakage, with subsequent activation of the nuclear enzyme poly (ADP-ribose) synthetase and eventual severe energy depletion of the cells.

High concentrations of NO donor agents have been shown to exacerbate the cytotoxic effect of hydrogen perox-

Figure 1 Cytotoxic actions of NO, formed from iNOS following its induction by lipopolysaccharide (LPS), on gastrointestinal epithelial cells. The cellular injury is brought about either by high concentrations of NO or by the combination of NO with the superoxide radical anion to form the cytotoxic moiety peroxynitrite.

ide in gastric mucosal cells and to be necessary for induction of mucosal injury by various types of intestinal bacteria. High levels of NO have also been shown to injure rat intestinal epithelial cells; this damage can be ameliorated by inhibitors of guanylate cyclase. Excessive levels of NO from endogenous or exogenous sources reduce gastric cellular viability, and this response appears to be related causally to an increase in intracellular Ca^{2+} . In isolated cells, the cytotoxic effect of NO has been found to be due to increased generation of oxidants as a result of a decrease in glutathione production. Furthermore, it has been demonstrated in isolated cells that high levels of NO can inactivate glutathione peroxidase, leading to increased accumulation of peroxides.

Infusion of NO donor agents to produce high local concentrations of NO can produce injury to the gastric mucosa. This damage is related to peroxynitrite formation and lipid peroxidation.

In the intestinal mucosa, excessive NO production is associated with increased vascular permeability (Fig. 2). The mechanism of this increased permeability appears to be associated with decreases in cellular cAMP levels, reduced levels of glutathione, and the formation of peroxynitrous acid.

In the gastrointestinal tract, induction of iNOS is associated with a reduction in cell viability. Furthermore, administration of extracts of *Helicobacter pylori* result in the induction of NOS and injury in duodenal cells.

Inducible NO Synthase and Inflammation

A large number of studies have identified increased expression and activity of iNOS in experimental models of inflammatory bowel disease as well as in human inflamed colonic, gastric, and esophageal tissue. The increase in NO synthase activity in experimentally induced colonic inflammation is related to an increase in neutrophil infiltration and subsequent tissue lipid peroxidation.

The inflammatory effect of increased levels of iNOS appears to be related to increased peroxynitrite activity. Administration of superoxide or peroxy scavengers reduces the ex-

tent of iNOS-mediated mucosal inflammation. Furthermore, nitrotyrosine, an index of peroxynitrite and nitrosylated proteins, can be detected in inflamed tissue from experimental animals and from humans with ulcerative colitis.

iNOS INHIBITION AND INFLAMMATION

Concurrent administration of NO synthase inhibitors that are not isoform selective with endotoxin challenge has been shown to substantially augment the early phase of microvascular injury in the gastrointestinal tract. In contrast, delay of administration of L-NMMA until 3 hours after endotoxin challenge reduced the subsequent vascular leakage at a time when inducible NOS activity becomes apparent. Thus the beneficial effect of delayed administration of L-NMMA and L-NAME is due to their ability to inhibit iNOS activity. The therapeutic efficacy of delayed administration of NOS inhibitors in intestinal injury models has been firmly established. Aminoguanidine, a putative iNOS inhibitor, while reducing the late phase vascular leakage induced by endotoxin, also enhances the early phase of mucosal and microvascular dysfunction in a manner similar to that seen after administration of nonisoform selective NOS inhibitors. Thus, the development of highly selective inhibitors of iNOS in the therapeutic control of intestinal inflammation is extremely important.

The putative iNOS-selective inhibitor S-methylisothiourea has been shown to ameliorate endotoxin-induced reductions in intestinal hyperpermeability and mucosal mitochondrial function, and the newly developed agent 1400W was found to be a potent and highly selective inhibitor of iNOS in intestinal dysfunction. In these studies 1400W had no detrimental effects on the early phase following endotoxin challenge while inhibiting the late phase injury. Administration of nonselective NOS inhibitors such as L-NAME or selective iNOS inhibitors such as S-(2-aminoethyl)isothiuronium bromide ameliorated experimentally induced colitis.

In contrast to the evidence that iNOS is cytotoxic and contributes to gut inflammation, a number of studies oppose this notion. In these studies elimination of high levels of NOS via knockout of the iNOS gene or via the use of selective iNOS antagonists did not reduce experimentally induced colitis. Similarly, other experimental studies have demonstrated that high levels of NO released from various NO donor agents did not cause breakdown of mucosal or microvascular barrier integrity under normal or inflammatory conditions. These are in contrast to a number of other studies demonstrating a marked injurious action of NO donor agents on the gastrointestinal mucosa.

It has been shown that NO released via iNOS expression following lipopolysaccharide administration can protect the gastric mucosa from damage in response to luminal irritants or stress and can protect the intestinal mucosa from an inflammatory challenge via a reduction in leukocyte infiltration and adhesion. This iNOS-mediated protection has also been attributed to an increase in cytoprotective release of PGE_2 , which acts as an antioxidant either directly for maintaining cellular glutathione or by activating other antioxidants such as manganese superoxide dismutase.

Figure 2 Induction of iNOS following challenge with lipopolysaccharide (LPS) leads to microvascular injury throughout the gastrointestinal mucosa, either as a result of high concentrations of NO or by a combination of NO and the superoxide radical anion to form the cytotoxic moiety peroxynitrite. The endothelial cell injury leads to the leakage of plasma proteins such as albumin into the interstitium.

In contrast to these results, the purified lipopolysaccharide derived from *Helicobacter pylori* can stimulate the expression of iNOS in duodenal cells; this event is associated with a cytotoxic action on these cells. This cellular injury can be ameliorated by iNOS inhibition as well as oxidant scavengers, suggesting the involvement of NO, superoxide, and subsequently peroxynitrite in the epithelial injury associated with *Helicobacter pylori* infection.

The involvement of NO in the tissue injury associated with infectious diseases of the gut has been explored. The intestinal inflammation associated with *Trichinella spiralis* infection can be reduced by L-NAME treatment, and the mucosal inflammation associated with shigellosis is closely related to epithelial iNOS expression. Furthermore, NO has been proposed as a primary etiologic factor in neonatal necrotizing enterocolitis. There is also involvement of iNOS in the chronic microvascular leakage and tissue inflammatory injury in the small intestine following administration of non-steroidal anti-inflammatory agents. This slowly developing enteropathy involves indigenous bacteria and is attenuated by inhibition of iNOS, suggesting that following ingress of bacteria, lipopolysaccharide is liberated in the intestinal mucosa, bringing about the induction of iNOS. It is possible that such inflammation will respond to the therapeutic use of selective iNOS inhibitors.

Conclusions

From this review, it is apparent that the involvement of NO in the physiology and pathology of the gastrointestinal tract is multifaceted. Despite the complexity, however, knowledge of the roles of NO in the gut may identify novel clinical utilities. The use of NO donor agents in a range of motility problems is currently under investigation, as is their use in protecting the gut mucosa from injury. Indeed, the therapeutic NO-containing nonsteroidal anti-inflammatory drugs are being actively pursued in experimental and clinical studies.

A wealth of literature supports the cytotoxic actions of NO in many different inflammatory situations, both in and beyond the gastrointestinal tract. Inhibitors of NO production are also being evaluated as anti-inflammatory agents in the gut. However, it is likely that NO produced from iNOS or its subsequent products are not involved in all aspects of the inflammatory response in the gut. In addition, the role of NO may well differ with the nature of the insult, the tissue, and environment involved. As with many other inflammatory mediators, it is entirely possible that a low level of expression of iNOS will reflect a possible host defense response to challenge, but that exaggerated or uncontrolled

expression of iNOS itself becomes detrimental. It is also feasible that the products of iNOS may have a greater role in the early phase of inflammation, such as following relapse in patients with inflammatory bowel disease, whereas lower levels of iNOS activity could have a beneficial action in the process of resolution in the inflammatory response. The NO pathway thus offers a number of diverse therapeutic opportunities for treating diseases of the gut.

IN THIS CHAPTER WE FOCUS OUR DISCUSSION ON THE PATHOPHYSIOLOGICAL EFFECTS OF NITRIC OXIDE (NO), OXYGEN FREE RADICALS, AND REACTIVE NITROGEN OXIDE SPECIES IN BIOLOGICAL SYSTEMS. WE PLACE PARTICULAR EMPHASIS ON HOST RESPONSES TO VARIOUS VIRAL AND BACTERIAL INFECTIONS AND TO SOLID TUMORS, IN VIEW OF CONSEQUENT PATHOLOGICAL MANIFESTATIONS THAT RESULT FROM REACTIVE NITROGEN OXIDE DERIVATIVES. THE DISCUSSION IS BASED PRIMARILY ON BIOCHEMICAL AND IMMUNOLOGICAL DATA, INCLUDING INDUCTION OF INDUCIBLE NO SYNTHASE AND PRODUCTION OF SUPEROXIDE ANION RADICAL AND PEROXYNITRITE. FURTHERMORE, THE DISCOVERY OF AN ACCELERATED VIRAL MUTATION RATE IN THE HOST DURING VIRAL INFECTION IS DISCUSSED FROM THE PERSPECTIVE OF NO-INDUCED OXIDATIVE STRESS. MECHANISMS OF CARCINOGENESIS INVOLVING FREE RADICALS FORMED IN THE COURSE OF CHRONIC INFECTIOUS DISEASES ARE ALSO DESCRIBED. IT APPEARS THAT THE MOST CRITICAL COMMON DENOMINATOR OF CARCINOGENESIS IS FREE RADICALS, WHICH ARE FORMED DURING MICROBIAL INFECTIONS, AFTER EXPOSURE TO CHEMICAL CARCINOGENS, AND BY ELECTROMAGNETIC RADIATION.

Introduction

Increasing attention has been paid to the pathogenic roles of nitric oxide (NO) produced in excess in various pathological settings. Both NO and reactive oxygen species such as superoxide anion radical (O_2^-), hydrogen peroxide (H_2O_2), and hypochlorite (HClO) are generated in inflamed tissues; in sites infected with viruses, bacteria, fungi, or parasites; and in cancerous tissues. These reactive species are generated mostly by inflammatory cells (macrophages and neutrophils), as well as by damaged tissue expressing xanthine oxidase (XO). Superoxide from macrophages, neutrophils, or various tissues will react extremely rapidly with NO to form reactive nitrogen oxides such as peroxynitrite ($ONOO^-$), which is more involved in pathogenesis than is NO per se

(Beckman and Koppenol, 1996; Rubbo *et al.*, 1996). The pathophysiological action of peroxynitrite, among various reactive nitrogen oxides, is of great interest for the pathogenesis of various diseases (Beckman *et al.*, 1990). Peroxynitrite is not only a potent oxidant but also a nitrating agent of various biological molecules such as proteins and nucleic acids as well as membrane lipids (Beckman and Koppenol, 1996; Rubbo *et al.*, 1996; Ischiropoulos, 1998). Thus, endogenously formed reactive nitrogen oxides appear to have a potential impact on mutagenesis and carcinogenesis as well as having other pathological consequences (Ohshima and Bartsch, 1994; Beckman and Koppenol, 1996; Rubbo *et al.*, 1996; Szabó and Ohshima, 1997).

In this chapter we describe various pathological effects of NO in view of the pathogenic potential of high-output

production of NO in inflammatory and infectious diseases and cancer, with the discussion based on experimental evidence obtained with animal models of inflammation, infection, and solid tumors (Maeda *et al.*, 1994; Akaike *et al.*, 1998; Maeda and Akaike, 1998; Wu *et al.*, 1998). We also discuss formation of reactive nitrogen species, particularly peroxynitrite, and their contribution to mutagenic and carcinogenic processes from the perspective of the unique and potent chemical reactivity of reactive nitrogen oxide species.

NO in Inflammation and Infections

It is now well known that superoxide and NO production is elevated in inflamed tissues. Generation of superoxide and active oxygen species is brought about by two components of the host response, namely, cellular reactions of leukocytes expressing NADPH oxidase (Clark, 1990) and humoral responses involving XO (Akaike *et al.*, 1990). The host reactions are in response to foreign matter, microorganisms, and damage caused by trauma, radiation, or ischemia–reperfusion injury. Because deficiency of an O_2^- -generating enzyme, NADPH oxidase, of phagocytic leukocytes is frequently associated with severe chronic bacterial infections (termed chronic granulomatous disease, CGD) (Tauber *et al.*, 1983), it is apparent that oxygen radical formation is important in front line host defense.

Overproduction of NO that is mainly caused by inducible NO synthase (iNOS), which is usually expressed by inflammatory phagocytic cells and other types of cells (e.g., epithelial and neuronal cells), has a similar defense function (Nathan and Hibbs, 1991; Nathan, 1997). Among the three types of nitric oxide synthase (NOS), iNOS produces a much larger amount of NO for a longer time (i.e., 10- to 100-fold more) than do the other two constitutive enzymes, neuronal NOS and endothelial NOS (Stuehr and Griffith, 1992; Moncada and Higgs, 1993). Although NO per se seems to have a limited bactericidal effect, suppression or lack of NO production results in impairment of bacterial clearance by the host (Yoshida *et al.*, 1993; de Groote *et al.*, 1995; Nathan, 1997; Akaike *et al.*, 1998). As a primary host defense mechanism, these free radical molecular species interact, and the reaction products of NO and superoxide indeed have a crucial role in various infections (Akaike *et al.*, 1998).

However, NO is not always beneficial to the host; it becomes detrimental to cells and tissues as well as to microbes. As discussed in more detail later, NO generated in inflamed tissue can cause injury through peroxynitrite formation. Not only is NO toxic to microbes, it is also hazardous to normal parenchymal tissue, possibly via cytotoxicity arising, for example, from the apoptotic and necrotic effects of peroxynitrite and other nitrogen oxides (Estevez *et al.*, 1995). Evidence of the pathophysiological effects of NO is illustrated in two different settings: granulomatous inflammation and microbial infections (Fig. 1).

Granulomatous Inflammation in the Lung

Experimental granulomatosis or fibrosis in the lung can be produced by intratracheal instillation of silica (Lugano *et al.*, 1982; Reiser *et al.*, 1982; Setoguchi *et al.*, 1996) or of various types of beads, such as dextran beads (Tsuji *et al.*, 1995), Sephadex G-50 beads (Kasahara *et al.*, 1988), or latex beads (Kasahara *et al.*, 1988), and by intravenous infusion of glucan (Jones and Warren, 1992; Flory *et al.*, 1993) or of microbes, such as *Mycobacterium tuberculosis* (Orrell *et al.*, 1992), bacille Calmette-Guérin (BCG) (Shellito and Sniezek, 1990), or *Schistosoma mansoni* (Lukacs *et al.*, 1993). Pulmonary granulomatous inflammation occurs predominantly as a focal collection of mononuclear phagocytes in response to a variety of microbes, foreign particulate matter, and etiologically unknown factors. In the acute phase of inflammation, infiltration of neutrophils into the lungs is one of the earliest events, followed by infiltration of monocytes, differentiation into exudate macrophages, and activation of these macrophages (Hunninghake *et al.*, 1984). In the chronic phase, tissue or resident macrophages show a marked proliferative reaction (Van Oud Albas *et al.*, 1983).

iNOS is upregulated in lung lesions via induction of proinflammatory cytokines, such as interleukin 1 β (IL-1 β), tumor necrosis factor α (TNF- α), and γ -interferon (IFN- γ), when silica or zymosan (mainly composed of β -glucan) is instilled intratracheally (Setoguchi *et al.*, 1996). Overproduction of NO in zymosan- or silica-instilled rat lungs is clearly observed by using electron spin resonance (ESR) spectroscopy. Because silica particles are toxic to and kill neutrophils and macrophages, the phagocytes containing the silica particles disintegrate, and the material is rephagocytosed by macrophages. This vicious circle is repeated and becomes a strong stimulus for granulomatosis and subsequent fibrosis in the lung. During these processes, silica particles remain undigested and further stimulate iNOS production in infiltrating leukocytes, macrophages (Setoguchi *et al.*, 1996; Blackford *et al.*, 1994), and bronchiolar epithelial cells (Tsuji *et al.*, 1995). Asbestos would produce similar effects *in vivo*.

Inhibition of NO synthesis results in reduced infiltration of monocyte-derived exudate macrophages into lung lesions in silica- and zymosan-induced granulomatosis, and zymosan particles remain undigested in zymosan-instilled lungs because of NOS suppression (Setoguchi *et al.*, 1996). Similarly, in a model of carrageenan sponge implantation, granuloma formation is potentiated by treatment with L-arginine, and granuloma growth is markedly reduced by an NOS inhibitor (N^G -nitro-L-arginine methyl ester, L-NAME) (Iuvone *et al.*, 1994). Certain chemokines such as monocyte chemoattractant protein-1 (MCP-1) are expressed in granulomatous inflammation (Jones and Warren, 1992; Flory *et al.*, 1993), and MCP-1 induces infiltration of monocyte-derived exudate macrophages. It is noteworthy that in lung lesions induced by silica and zymosan NOS inhibition reduces MCP-1 expression at the protein and messenger RNA (mRNA) levels, suggesting that NO induces MCP-1 in lung granulomas

Figure 1 Biological effects of high output of NO in granulomatous inflammation and microbial infections. Foreign particulate matter, such as silica and bacteria, is physically contained in the local area of inflammation, as shown in the middle and right, respectively. Nonselective cell and tissue injury tends to occur in viral infections and granulomatous lesions, whereas bacteria can be eradicated by NO-dependent host defense actions.

via NO-dependent putative transcription or translation of MCP-1 (Setoguchi *et al.*, 1996).

Macrophages produce superoxide anion after stimulation with zymosan and silica (Berton and Gordon, 1983; Vallyathan *et al.*, 1988), and thus simultaneous generation of superoxide anion and NO, leading to peroxynitrite formation, occurs in granuloma tissues. This result is supported by intense positive immunostaining directed at nitrotyrosine in neutrophils, macrophages, and intra-alveolar inflammatory exudate in granulomas (Setoguchi *et al.*, 1996). We found that peroxynitrite activates human neutrophil procollagenase (matrix metalloproteinase 8, MMP-8), which is critical in tissue disintegration and remodeling under physiological as well as pathological conditions such as inflammation and infection (Okamoto *et al.*, 1997a, b). In addition to activating MMP-8, peroxynitrite readily inactivates both tissue inhibitor of metalloproteinase (TIMP) and α_1 -proteinase inhibitor (α_1 -PI), the major proteinase inhibitor of neutrophil elastase, which exists in large quantity (i.e., 2–3 mg/ml) in human plasma (Moreno and Pryor, 1992; Frears *et al.*, 1996; Whiteman *et al.*, 1996). Thus, peroxynitrite seems to accelerate tissue degradation and contribute to the pathogenesis of various diseases. It is intriguing that peroxynitrite activates cyclooxygenase, a key enzyme in the production of the potent

inflammatory mediators, the prostaglandins (Landino *et al.*, 1996). Our experiment shows that activation of proMMP also appears to trigger formation of bradykinin, which is a potent inflammatory mediator (T. Akaike and H. Maeda, 2000, unpublished observation). Therefore, peroxynitrite may sustain granuloma extension via both tissue-remodeling actions on pulmonary connective tissues and proinflammatory effects.

These data indicate that excessive production of NO mediated through the action of iNOS induced by foreign particulates probably contributes to the development of pulmonary granulomatosis (Fig. 1). More importantly, NO produced in excess by iNOS seems to function as an inflammatory mediator (Clancy and Abramson, 1995; Kubes, 1995), possibly through the diverse biological actions of peroxynitrite. In this context, it is interesting that peroxynitrite exacerbates airway hyperpermeability during the allergic response of bronchial asthma (Sugiura *et al.*, 1999).

Overproduction of NO in Microbial Infections

NO IN VIRAL INFECTIONS

iNOS is induced in a variety of experimental viral infections in rats and mice, including those with neuroviruses, such as Borna disease virus, herpes simplex virus type 1

Figure 2 Typical pathological changes in virus-infected tissues expressing iNOS and NO. (A) iNOS immunostaining of lung infected with Sendai virus (2 LD₅₀; 8 days after infection; magnification, $\times 230$). Intensive staining is observed mainly in phagocytic cells such as macrophages infiltrating the alveoli and interstitial tissues. (B) NO signal as identified by ESR spectroscopy at 110 K as an NO dithiocarbamate-iron complex adduct generated in the same virus-infected lung. Approximately 10–20 μ M of the NO adduct is usually obtained from the infected lung tissues. The chemical structure of the adduct is also shown.

(HSV-1), and rabies virus, and pneumotropic and cardiotropic viruses, such as influenza virus, Sendai virus, and Coxsackie virus (Koprowski *et al.*, 1993; Zheng *et al.*, 1993; Campbell *et al.*, 1994; Akaike *et al.*, 1995, 1996, 1998; Bi *et al.*, 1995; Kreil and Eibl, 1996; Mikami *et al.*, 1996).

In the case of pneumotropic virus infections in mice, iNOS is expressed by exudate macrophages and bronchial epithelial cells in lung tissues, and the high output of NO in virus-infected lesions is evident by ESR spin trapping with the use of a dithiocarbamate-iron complex (Fig. 2) (Akaike *et al.*, 1996; Akaike and Maeda, 1999). In general, the time profile of iNOS induction in the lung correlates well with that of pulmonary consolidation rather than that of virus replication in the lung. Virus replication reaches a maximum 3 to 4 days after infection, whereas NO production reaches a maximum on days 7 to 8, when the viral count is almost undetectable. Pathological manifestations as determined by the consolidation score parallel the NO production. Lethality in the mice starts to increase on day 8 after viral infection.

iNOS induction in this pneumotropic virus infection is mediated by proinflammatory cytokines such as IFN- γ , as in many other inflammatory diseases as mentioned above. Induction of IL-4 becomes detectable in virus-infected lung as early as 2 days after infection, and it increases steadily, attaining a maximum value 6 days after infection. The level of IL-4 in plasma increases rapidly more than 8 days after infection. NO production in the lung is seen only 6 to 9 days after infection, corresponding to the appearance of pathological changes. It is also important to note that induction of arginase I mRNA has been identified in virus-infected lung,

paralleling IL-4 induction in the plasma (T. Akaike and H. Maeda, 2000, unpublished observation).

Downregulation of iNOS expression is reported for some cytokines, for example, IL-4, IL-10, and transforming growth factor β (Cunha *et al.*, 1992; Vodovotz *et al.*, 1993; Bogdan *et al.*, 1994); a suppressive effect of IL-4 and IL-10 on iNOS mRNA induction has been shown in murine macrophages in culture. In addition, these suppressor cytokines may reduce NO production indirectly via induction of arginase (Corraliza *et al.*, 1995; Gotoh *et al.*, 1996; Sonoki *et al.*, 1997), which diminishes the supply of substrate (L-arginine) for this enzyme. It is known that IL-4 and IL-10 are involved in the stimulation and differentiation of B cells so that they produce antibody, through a Th2 response pathway (Wright, 1997). It seems, therefore, that suppressor cytokines for iNOS induction switch the NO-dependent host response to a virus-specific humoral immune response against the intruding virus.

NO has an antiviral action, although its selective antiviral toxicity is still controversial. A number of experiments have verified that simultaneous production of NO and superoxide is common in influenza virus pneumonia in mice (Akaike *et al.*, 1996, 1998). For example, induction of iNOS correlates with XO upregulation in infected lung. When superoxide generated in the lung is removed by intravenous administration of superoxide dismutase (SOD) derivatized with a synthetic polymer to remain in circulation more than 10 times longer than native SOD, NO production in virus-infected tissue apparently increases, as identified by ESR spectroscopy (Akaike *et al.*, 1996). In addition, extensive immunostaining of virus-infected lung with antinitrotyrosine antibody

suggests that peroxynitrite is generated in inflammatory tissue during pneumonia (Akaike *et al.*, 1996).

Overproduction of NO together with superoxide production yielding peroxynitrite nonselectively impairs the physiological functions of the host cells regardless of the source of infection. In fact, we showed that neither inhibition of NO biosynthesis nor scavenging of superoxide and inhibition of its production affects virus yield in lungs infected with influenza virus. However, a significant improvement in lung pathology and survival rate of the influenza virus-infected animals is obtained by treatment with the NOS inhibitor *N*^ω-monomethyl-L-arginine (L-NMMA) or superoxide antidotes such as pyran-conjugated SOD, or with an inhibitor of XO, allopurinol. The contribution of high-output NO to influenza pathogenesis was also verified by Karupiah *et al.* (1998) using mice lacking iNOS: virus-induced pneumonia in iNOS-deficient mice is much less severe than that in wild-type mice. A similar result was obtained by Kreil and Eibl (1996), who used an NOS inhibitor in tick-borne encephalitis virus infection in mice. Although an antiproliferative action of NO against HSV has been described for cells in culture (Karupiah *et al.*, 1993; Croen, 1993), our results *in vivo* indicate that suppression of excessive production of NO by L-NMMA in the central nervous system of HSV-1-infected animals results in improvement of neuronal damage, but suppression of NO generation does not affect virus propagation (Fujii *et al.*, 1999). Similarly, improvement of HSV-1-induced pneumonia by L-NMMA was reported by Adler *et al.* (1997).

Moreover, iNOS expression has been found in brain tissue of a patient with severe human immunodeficiency virus-1 (HIV-1) encephalitis (Bukrinsky *et al.*, 1995). A viral envelope glycoprotein of HIV, gp41, triggered iNOS expression in human astrocytes and murine cortical brain cells in culture (Adamson *et al.*, 1999; Hori *et al.*, 1999). Of considerable importance is the finding that NO produced by iNOS causes neuronal cell death, suggesting involvement of NO in the pathogenesis of HIV-associated dementia and its related central nervous system injury (Bukrinsky *et al.*, 1995; Adamson *et al.*, 1999; Hori *et al.*, 1999; Boven *et al.*, 1999).

All the results just described suggest that the overproduction of NO induced by iNOS in virus infections is critical in the pathogenesis of these infections, rather than the functioning of NO as a specific antiviral molecule in host defense (Fig. 1). Viruses usually attack tissue indiscriminantly, and many types of viruses propagate and spread not only from cell to cell but also by free diffusion in tissues. Thus, the physical containment strategy in host defense is mostly ineffective against viral pathogens. Free radical effector molecules such as NO and superoxide produced by the host in defense will assault both normal cells and tissues and virus-infected cells, and thus the detrimental effects of NO production and peroxynitrite formation outweigh any benefits to the host (Fig. 1).

ANTIMICROBIAL EFFECT OF NO

The pathogenic effect of NO and superoxide in virus infections appears to be in clear contrast to the antimicrobial

actions of NO and superoxide observed in bacterial, fungal, and parasitic infections (Granger *et al.*, 1988; Nathan and Hibbs, 1991; Doi *et al.*, 1993; James, 1995; Umezawa *et al.*, 1995, 1997; Nathan, 1997). NO overproduction is suggested to cause lipopolysaccharide (LPS)-induced lung injury (Kristof *et al.*, 1998) and neurological damage in bacterial meningitis in children (Kornellisse *et al.*, 1996). Bacterial infections are also known to induce iNOS expression in septic foci and sites of inflammation. In this case, bacterial cell components, namely, LPS and teichoic acid, may be involved directly or indirectly through induction of a series of proinflammatory cytokines during the infection.

Although the antibacterial action of NO was proposed by Hibbs and co-workers a long time ago (Granger *et al.*, 1988), NO *per se* seems rather inert up to the millimolar concentration (Yoshida *et al.*, 1993; de Groote *et al.*, 1995). This effect may be more pronounced in phagocytosed cells. In our experiments, peroxynitrite or NO₂ exhibited far greater (100-fold more) bactericidal action, whereas NO released from an NONOate [1-hydroxy-2-oxo-3-(*N*-methyl-3-aminopropyl)-3-methyl-1-triazene] or authentic NO dissolved in water showed only a marginal effect at 1 mM (Yoshida *et al.*, 1993; Kuwahara *et al.*, 2000). It is interesting in this context that *S*-nitrosylated α₁-PI, a major protease inhibitor in human plasma, becomes 10- to 100-fold more bacteriostatic than NO or *S*-nitroglutathione on a molar basis (Miyamoto *et al.*, 2000a, b).

The antimicrobial effect of NO and superoxide *in vivo* is most clearly observed in a study of *Salmonella typhimurium* infection in mice, in which XO and iNOS are strongly upregulated as part of the host defense reaction, similar to the situation in virus infections (Umezawa *et al.*, 1997). The most primitive host defense response is physical containment of the intruding pathogens to a confined area. Containment of the pathogen is typically characterized as a pathological change, that is, abscess or granuloma formation. In the case of murine salmonellosis, multiple microabscesses showing a clear contour are observed in livers infected with *S. typhimurium* (Umezawa *et al.*, 1995, 1997). The bacteria are contained by phagocytes (such as neutrophils and macrophages) in localized septic lesions. As a result, reactive molecular species, for example, NO, superoxide, OCl⁻, hydrogen peroxide (H₂O₂), and peroxynitrite, directly affect invading pathogens only in the confined area, and most commonly intracellularly, so that effective cytotoxic action against pathogens but minimal tissue injury in the surrounding area will occur during the defense process of the host (Fig. 1).

Mutagenesis and Carcinogenesis Caused by High-Output NO

The mutagenic potential of free radicals and peroxynitrite has been reported (Vuillaume, 1987; Ohshima and Bartsch, 1994; Liu and Hotchkiss, 1995; Szabó and Ohshima, 1997).

It is thus of paramount importance to explore a link between excessive generation of NO and superoxide and carcinogenesis.

NO and Carcinogenesis

Oxidation of NO by any mechanism results in generation of various nitrogen oxide derivatives. It has been known since the 1960s that nitrous acid damages nucleic acids by deamination (Fraenkel-Conrat, 1964); therefore, it follows that mutation and hence carcinogenesis are initiated by free radicals and nitrogen oxides. Peroxynitrite formed by the reactions of NO and superoxide and reactive nitrogen oxides including nitrogen dioxide (NO₂) are the most crucial molecular species.

Classic textbooks in oncology or pathology describe three completely different causes of cancer: chemical carcinogens (or chemicals such as heterocyclic amines), infections with tumor viruses such as simian virus 40 (SV40), and exposure to radiation such as X rays, γ rays, and ultraviolet light (see Fig. 3). The last one, radiation, is the oldest known carcinogenic factor involving the generation of free radicals in radiation physics. Hydroxyl radical, superoxide, and singlet oxygen are generated by electromagnetic interaction between water or oxygen molecules, and they react with nucleic acids, proteins, membrane lipids, and other biomolecules. The damage to nucleic acids causes mutation, with the consequent development of cancer. The existence of radicals such as superoxide in biological systems has become well known. As described earlier, we now have ample evidence that microbial or parasitic infections and inflammatory conditions can generate free radicals as well as reactive oxygen and nitrogen oxide intermediates. In different settings, we have observed that chemical carcinogens, for example, heterocyclic amines, can generate superoxide in the presence of the cytochrome P-450 system or cytochrome P-450 reductase and, more recently, cytochrome *b₅* reductase (Sato *et al.*, 1992; Maeda *et al.*, 1999). Thus, one of the best studied carcinogens, the heterocyclic amine found in cooked meat and fish, is a source of superoxide generation. In addition, 8-hydroxyguanine (8OHG) generation, as a result of the reaction with hydroxyl radical, is now established (Kasai and Nishimura, 1984).

Among the reactive molecular species that might injure nucleic acids, superoxide and NO are regarded as the most important. In fact, it is conceivable that peroxynitrite can oxidize DNA (Inoue and Kawanishi, 1995; Spencer *et al.*, 1996) and nitrate DNA, particularly its guanine residue to form 8-nitroguanine (Yermilov *et al.*, 1995a; Spencer *et al.*, 1996). Nitroguanine is then spontaneously released from DNA, resulting in apurinic site formation (Yermilov *et al.*, 1995b). H₂O₂ is also important unless converted to H₂O and O₂ by catalase, because H₂O₂ can be the source of the more reactive hydroxyl radical (\cdot OH) via the Fenton reaction in the presence of transition metals in biological systems (Halliwell and Gutteridge, 1984). Another important alternative mechanism involves H₂O₂ and the myeloperoxidase-catalyzed

Figure 3 Central themes and universal mechanisms in carcinogenesis: Interaction of free radicals and DNA in infection and inflammation, and with carcinogens, leads to cancer.

pathway, which generates NO₂Cl and NO₂ in the presence of NO₂⁻, which results in nitration or chlorination of tyrosine and guanine residues of protein and DNA (Eiserich *et al.*, 1998; Byun *et al.*, 1999).

As mentioned earlier in this chapter, not only defense-oriented phagocytic cells such as macrophages and polymorphonuclear cells but also endothelial and epithelial cells are activated to produce free radical species, most commonly in microbial infections or because of stress or other insult to the host. Once these reactive molecular species (or free radicals) are generated during the inflammatory responses of the host, they can damage DNA, enzymes and proteins, and other vital molecules. Some oxygen radicals such as the hydroxyl radical, which is highly reactive and short-lived, may be converted to more stable lipid peroxide radicals (LOO \cdot), with longer half-lives, which would travel long distances *in vivo* and may accumulate in fat-rich organs and cellular microenvironments (Akaike *et al.*, 1992; Sawa *et al.*, 1998).

Several epidemiological studies suggest a link between infections and carcinogenesis (see Table I). The importance of free radicals in carcinogenesis is increasing as the evidence of excessive production of NO and oxygen radicals in infections and inflammation accumulates (Vuillaume, 1987; Yuspa and Poirier, 1988; Harris, 1991). Thus, although the free radical theory played a rather minor role in previous studies of cancer etiology, it now appears more realistic in view of more recent findings of the generation of superoxide, peroxynitrite, and NO in infectious diseases.

In the history of infection-related carcinogenesis, many efforts have focused on tumor viruses with the viral oncogene or *v-onc*. However, carcinogenesis induced by viruses (and also bacteria) does not involve the so-called *v-onc*; most such agents (hepatitis viruses B and C, herpes simplex type II, *Helicobacter pylori*, and *Schistosoma*, as shown in Table I) are devoid of *v-onc*. The most common factor is that these infections involve chronic inflammation, in which long-term exposure of the host organism, mostly for more than 10 years, to both nitrogen- and oxygen-related free radicals may cause mutation of the hot spot of certain genes such as p53 and other tumor suppressor genes.

Table I Infection-Related Carcinogenesis Caused by Various Infectious Agents

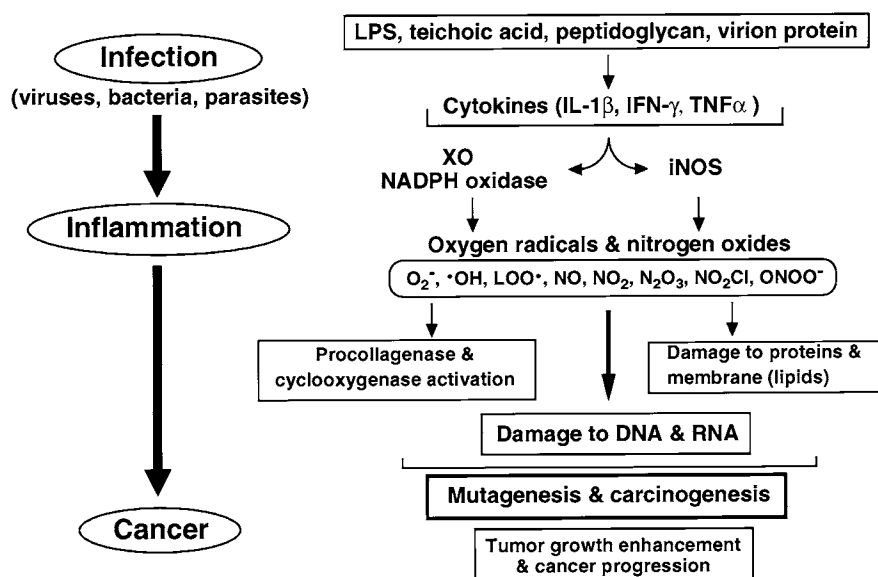

Agent	Cancer
Bacteria	
<i>Helicobacter pylori</i>	Gastric cancer (gastritis/ulcer)
<i>Salmonella typhi</i> , <i>S. paratyphi</i> A, B	Gallbladder cancer, pancreatic cancer
Viruses	
Hepatitis virus types B and C	Hepatoma (chronic hepatitis/cirrhosis)
Herpes simplex virus type 2	Cervical cancer (recurrent infection)
Epstein-Barr virus	Gastric cancer, nasopharyngeal cancer (Burkitt lymphoma)
Papillomaviruses	Cervical cancer
Polyomaviruses (e.g., SV40, JCV)	Brain cancer?, tumors at multiple sites
Human T-cell leukemia virus	Adult T-cell leukemia
Parasites	
<i>Opisthorchis viverrini</i>	Cholangiocarcinoma (cholangiofibrosis)
<i>Schistosoma</i> species	Bladder cancer, hepatoma

The cause-and-effect relationship of *H. pylori* infection and gastric cancer appears to be of great interest in this context. Gastric cancer is one of the major cancers in Japan as well as in many developing countries. It now appears to be caused by a spiral bacterium, *H. pylori* (Sugiyama *et al.*, 1998; Honda *et al.*, 1998). *Helicobacter pylori* can cause a chronic infection, manifested frequently as gastritis and gastric ulcer. Baik *et al.*, (1996) reported pronounced DNA damage, particularly formation of 8OHG, in human gastric mucosa with chronic *H. pylori* infection, providing additional *in vivo* evidence that infections cause DNA damage. Induction of iNOS and production of nitrotyrosine are also found in *H. pylori*-infected human mucosa (Mannick *et al.*, 1996; Pignatelli *et al.*, 1998). In chronic typhoid and paratyphoid carriers infected with *Salmonella typhi* or *S. paratyphi* A or B, the incidence of cancers of the gallbladder and pancreas is also reported as high (Caygill *et al.*, 1994).

This may be another example of cancer involving bacterial infections.

Moreover, various agents, including hepatitis B and C viruses, Epstein-Barr virus, and parasites (*Opisthorchis viverrini* and *S. mansoni*), have been suggested to be risk factors for hepatoma, gastric cancer, and other types of cancer (Table I). The cause of this risk may be closely related to the formation of free radicals and reactive nitrogen oxides, particularly peroxynitrite (Ohshima and Bartsch, 1994).

We have presented here examples of free radical generation in viral and bacterial infections that would result in consequences similar to those of radiation and chemical carcinogens. The free radical hypothesis in carcinogenesis seems to unify all of these different carcinogenic mechanisms, as summarized in Fig. 4. Preventive measures for cancer may thus include minimizing excessive exposure to free radicals *in vivo* by dietary uptake of various antioxidants, for exam-

**Figure 4** Various events involving free radicals in infection and inflammation that lead to cancer.

ple, a diet high in flavonoids, by adequate anti-inflammatory regimens, or by control of chronic infections.

Mutagenesis in Microbial Pathogens Induced by NO-Derived Metabolites

Among the NO-induced pathological effects, the mutagenic potential of NO in microbial pathogens is also intriguing. One study showed that human leukocytes producing superoxide, but not leukocytes from patients with CGD, are mutagenic for *S. typhimurium* TA100 (Weitzman and Stosel, 1981). Peroxynitrite is mutagenic for prokaryotic DNA, possibly via its nitration of guanine residues of DNA. A typical base substitution caused by peroxynitrite is G → T transversion, which is an indirect result of depurination of nitroguanine in DNA (Yermilov *et al.*, 1995b; Juedes and Wogan, 1996). Mutagenesis induced by a high output of NO is also documented in a study with murine macrophages expressing iNOS (Zhuang *et al.*, 1998).

As mentioned earlier, overproduction of NO and oxygen radicals appears to be a common phenomenon in various infections. The resultant reactive molecular species such as peroxynitrite nonselectively affect the cells and tissues of the host. Such host defense effectors are originally produced to injure the intruding pathogens, which will then suffer oxidative stress because of the host. Therefore, it may be that mutagenesis in various pathogens occurs naturally in biological systems during infections as a result of host defense.

For viral mutation, it is of potential interest to investigate a possible association of oxidative stress and virulence of viruses. Beck *et al.* (1995) show that the pathogenicity of coxsackie virus B3 is strongly potentiated *in vivo* in mice fed a selenium-deficient diet. More importantly, an avirulent strain of the virus is converted to a potent cardiotoxic variant during infection in selenium-depleted animals. The deficiency of selenium may result in an ineffective antioxidant system, for example, low levels of glutathione peroxidase. These studies were extended to vitamin E- and glutathione peroxidase-deficient animals, and the results suggest that oxidative stress facilitates selection and generation of virulent mutants (Beck *et al.*, 1998). Although the molecular mechanism for the conversion of avirulent to virulent strains of coxsackie virus *in vivo* is unclear, impaired immunological clearance due to reduced levels of antioxidants may cause an increased incidence of heterogeneous mutants of the virus, resulting in selection of highly pathogenic variants.

In addition, our study verifies for the first time that oxidative stress induced by high-output NO accelerates RNA virus mutations (T. Akaike *et al.*, 2000). In brief, by using a recombinant RNA virus, Sendai virus (a negative-sense and single-strand RNA virus) containing a marker gene for genetic mutation, and iNOS knockout mice, we obtained solid and direct evidence showing that overproduction of NO in the hosts (wild-type mice) *in vivo* apparently increases and accelerates viral mutation rates compared with the situation in iNOS-deficient mice. This process of accelerated mutation expands the heterogeneity of variants

of the pathogen, leading to rapid evolution under selective pressure. NO and superoxide and hence peroxynitrite generation occurs universally in infected hosts. This finding therefore has great implications for RNA virus evolution in general, including the rapid generation of drug-resistant and immunologically tolerant and cell tropism-altered mutants of HIV *in vivo*.

NO and Solid Tumor Growth

Enhancement of Tumor Growth by NO

In this section, we describe the pathophysiological effects of NO in relation to tumor growth. Rapid tumor growth requires an adequate supply of nutrients and oxygen from circulating blood. This nutrient demand is sustained via enhanced vascular permeability in solid tumor tissues, which is mediated by a number of factors derived from tumor cells or from the host tissue, including NO, bradykinin, and vascular permeability factor (VPF; also called vascular endothelial growth factor, VEGF) (Senger *et al.*, 1983; Matsumura *et al.*, 1988; Vaupel *et al.*, 1989; Maeda *et al.*, 1994; Nakano *et al.*, 1996; Suzuki *et al.*, 1996; Wu *et al.*, 1998). Maintenance of regional blood flow in solid tumor tissues appears to be most important for tumor cell growth (Kallinowski *et al.*, 1989). NO released from vascular endothelial cells plays an important physiological role in the regulation of blood flow in the systemic circulation via its potent vasodilating action (Furchgott and Vanhoutte, 1989; Ignarro, 1991; Moncada and Higgs, 1993). Solid tumor growth may therefore be sustained by increased blood flow mediated by prolonged and excessive production of NO.

We have previously demonstrated that NO functions as a vascular permeability factor (Maeda *et al.*, 1994). Furthermore, a number of studies show that tumor neovasculature is highly defective in its architecture; for example, smooth muscle cells are lacking and angiotensin II receptors are missing. Vascular density in tumors is also higher than in normal tissues. All of these result in enhanced vascular permeability in solid tumors. This means that tumor blood vessels are quite leaky: even albumin and other macromolecules can move out of the vessels. The L-arginine-dependent NO pathway mediates angiogenic activity not only in normal tissues (Leibovich *et al.*, 1994) but also in solid tumors (Jenkins *et al.*, 1995). It is intriguing that Ziche *et al.* (1997) reported that VEGF (VPF) induces angiogenesis via formation of NO. Angiogenesis leading to hypervascularization is most frequently associated with rapid tumor growth. NO-aided tumor growth has been shown in tumor-bearing mice, in which human adenocarcinoma cells overexpressing iNOS were implanted and NO-induced angiogenesis led to acceleration of tumor growth *in vivo* (Jenkins *et al.*, 1995). Promotion of tumor progression and metastasis by NO is also suggested by structural evidence (Lala and Orlucevic, 1998; Thomsen and Miles, 1998).

Other important factors that affect the vascular permeability of solid tumors include bradykinin, as discussed earlier

(Maeda *et al.*, 1988, 1996). We now know that the inhibition or scavenging of NO or bradykinin results in suppression of permeability and of tumor growth, whereas vascular permeability is proportional to tumor growth (Maeda *et al.*, 1994; Doi *et al.*, 1996, 1999; Nakano *et al.*, 1996; Thomsen *et al.*, 1997; Tozer *et al.*, 1997; Wu *et al.*, 1998). Because bradykinin, which triggers NO release from endothelial cells (Palmer *et al.*, 1988), is generated effectively in tumors (Matsumura *et al.*, 1988; Maeda *et al.*, 1996), the bradykinin–NO interaction may be important in tumor growth.

The tumor-infiltrating activated macrophage is a major contributor to overproduction of NO in solid tumors, although some tumor cells can also generate NO. A particularly high output of NO from iNOS is potentially cytotoxic for various tumor cells (Hibbs *et al.*, 1988; Bastian *et al.*, 1994; Lepoivre *et al.*, 1994). Therefore, NO has two opposite effects in tumor biology, i.e., suppression and promotion of tumor growth. These discrepant actions may be explained by a putative mechanism in tumor cells that protects against the cytotoxicity of excess NO.

Heme Oxygenase as a Potent Protective Effector for NO Cytotoxicity

Of considerable interest is a unique biological function of heme oxygenase (HO), which is involved in catabolic breakdown of heme compounds in iron metabolism (Tenhunen *et al.*, 1968). HO degrades heme to release carbon monoxide (CO), iron, and biliverdin (Maines, 1997). Two isoforms of HO, namely, HO-1 and HO-2, are known to exist in eukaryotic systems (Maines and Kappas, 1974). HO-1 is induced by various stimuli, such as proinflammatory cytokines and heavy metals (Shibahara *et al.*, 1985; Maines, 1997; Yet *et al.*, 1997). Induction of HO-1 has been suggested to result in an important protective response of cells against oxidative damage, because HO-1 induction may decrease the cellular heme level (pro-oxidant) and elevate the level of bilirubin (anti-oxidant), which is derived from biliverdin and is a potent scavenger of reactive oxygen species (Kim *et al.*, 1995a, b; Maines, 1997). Lancaster and co-workers reported that pretreatment of rat hepatocytes with a low dose of NO donor agent confers resistance to cellular oxidative damage through induction of HO-1 (Kim *et al.*, 1995a). Their report also demonstrated that HO-1 induction protects the cells from NO-mediated cytotoxicity. HO-1 has been shown to be constitutively expressed in the liver and spleen and in some tumor cells (Tenhunen *et al.*, 1968; Shibahara *et al.*, 1985; Lee and Ho, 1994; Goldman *et al.*, 1996; Hara *et al.*, 1996; Maines, 1997). In addition, it is proposed that CO, a product of HO, functions as a gaseous signal transduction molecule in a manner similar to that of NO (Suematsu *et al.*, 1995; Maines, 1997; Prabhakar *et al.*, 1997).

HO expression is highly upregulated in some experimental and human solid tumor tissues (Lee and Ho, 1994; Goldman *et al.*, 1996; Hara *et al.*, 1996; Takahashi *et al.*, 1996). For example, HO-1 is constantly upregulated in a solid tumor model in rats (Doi *et al.*, 1999). The level of HO-1 mRNA

expression is apparently enhanced in AH136B tumor cells in culture by treatment with an NO (NO⁺) donor agent. Regulation of HO-1 expression by NO is also verified in AH136B tumor-bearing rats *in vivo*, as revealed by suppression of HO-1 induction by treatment of the animals with an NOS inhibitor. Also, hypoxia causes HO-1 induction. Intraarterial administration of the HO inhibitor Zn-protoporphyrin IX strongly suppresses AH136B tumor growth *in vivo* (Doi *et al.*, 1999). On the basis of these findings, the upregulation of HO-1 is thought to have protective and beneficial effects for tumor cells against the antitumor actions of NO derived from the host as well as of many anticancer agents.

Concluding Remarks

The pathophysiological effects and consequences of NO produced in excess in inflammatory or infectious tissue are described in this chapter, with special emphasis on infections, cancer, and mutagenesis. The biological and biochemical activities of reactive nitrogen oxides such as peroxynitrite, via interplay of NO with superoxide and active oxygen species, are of paramount interest, because NO and its oxidized derivatives have diverse functions not only as inflammatory mediators but also as inter- and intracellular signaling molecules. Also, the nitrogen oxides produced via high-output NO may be involved in carcinogenesis as well as mutagenesis. NO-induced oxidative stress might affect the mutation and evolution of various pathogens directly, possibly through peroxynitrite formation. Improved understanding of NO-related molecular pathogenesis will help in the exploration of novel therapeutic strategies.

Acknowledgments

The authors thank Ms. Judith Gandy for editing and Ms. Rie Yoshimoto for preparing the manuscript. Thanks are due also to Drs. Motohiro Takeya and Kiyoshi Takahashi, Department of Pathology, Kumamoto University School of Medicine, for helpful comments and discussions of the immunohistochemical analysis. This work was supported by a Grant-in-Aid for Research on Cancer from the Ministry of Education, Culture, Sports, and Science of Japan.
